Kinetic control on diatom Zn isotopes

20 **Abstract**

21 Marine diatoms dominate the oceanic cycle of the essential micronutrient zinc (Zn). The stable
22 isotopes of zinc and other metals are increasingly used to understand trace metal micronutrient
23 cycling in the oceans. One clear feature of the early isotope data is the heavy Zn isotope signature
24 of the average oceanic dissolved pool relative to the inputs, potentially driven by uptake of light
25 isotopes into phytoplankton cells and export to sediments. However, despite the fact that diatoms
26 strip Zn from surface waters across the Antarctic polar front in the Southern Ocean, the local
27 upper ocean is not isotopically heavy. Here we use culturing experiments to quantify the extent
28 of Zn isotope fractionation by diatoms and to elucidate the mechanisms driving it.

29 We have cultured two different open-ocean diatom species (*T. oceanica* and *Chaetoceros sp.*) in
30 a series of experiments at constant medium Zn concentration but at bioavailable medium Fe
31 ranging from limiting to replete. We find that *T. oceanica* can maintain high growth rates and Zn
32 uptake rates over the full range of bioavailable iron (Fe) investigated, and that the Zn taken up
33 has a $\delta^{66}\text{Zn}$ that is unfractionated relative to that of the bioavailable free Zn in the medium. The
34 studied representative of the genus *Chaetoceros*, on the other hand, shows more significantly
35 reduced Zn uptake rates at low Fe and records more variable biomass $\delta^{66}\text{Zn}$ signatures, of up to
36 0.85 ‰ heavier than the medium. We interpret the preferential uptake of heavy isotopes at
37 extremely low Zn uptake rates as potentially due to either of the following two mechanisms.
38 First, the release of extracellular polymeric substances (EPS), at low Fe levels, may preferentially
39 scavenge heavy Zn isotopes. Second, the Zn uptake rate may be slow enough to establish pseudo-
40 equilibrium conditions at the transporter site, with heavy Zn isotopes forming more stable surface
41 complexes.

42 Thus we find that, in our experiments, Fe-limitation exerts a key control that not only limits
43 diatom growth, but also affects the Zn uptake physiology of diatoms. Uptake of heavy isotopes
44 occurs under Fe-limiting conditions that drive extremely low Zn uptake rates. On the other hand,
45 more rapid Zn uptake rates result in biomass that is indistinguishable from the external
46 bioavailable free Zn pool. These experimental results can, in principle, explain the range of Zn

- 47 isotopic compositions found in the real surface ocean, given the geographically variable interplay
- 48 between Fe-limitation, Zn uptake rates, and the degree of organic complexation of oceanic Zn.

49 **1. Introduction**

50 Transition metals, such as zinc (Zn) and iron (Fe), show nutrient-like depth profiles in the ocean,
51 characterized by extreme photic zone depletion and deep enrichment (*e.g.* Bruland, 1980; Martin
52 et al., 1989). Zn cellular abundances exceed those of Fe in a key phytoplankton group, the
53 diatoms (Morel et al., 2003; Twining and Baines, 2013). The jury is still out, however, on whether
54 Zn concentrations in the photic zone of the oceans are ever low enough to limit phytoplankton
55 growth (*e.g.* Crawford et al., 2003; Moore et al., 2013), as has been found to be the case for Fe
56 in high nutrient low chlorophyll (HNLC) zones like the Southern Ocean (see review by Boyd
57 and Ellwood, 2010).

58 Recently, stable isotope systems have begun to be harnessed as tools in attempts to understand
59 the oceanic distributions of transition metals and in particular their participation in
60 biogeochemical cycles (*e.g.* Bermin et al., 2006; Abouchami et al., 2011; Conway and John,
61 2014b, a; John and Conway, 2014; Zhao et al., 2014; Conway and John, 2015a, b). For Zn, the
62 focus here, some important first-order features of the stable isotope distributions are emerging.
63 The first is that Zn stable isotopes exhibit remarkable homogeneity beneath the permanent
64 thermocline, with $\delta^{66}\text{Zn}_{\text{JMC 3-0749}}$ around +0.5 ‰. This isotopic composition is slightly but
65 significantly heavier than the known inputs to the oceans, but much lighter than some of the well-
66 characterized sedimentary outputs, such as those associated with Fe-Mn oxides, as well as
67 carbonate and opaline sediments (Little et al., 2014). Recent findings of isotopically light
68 authigenic Zn in organic-rich sediments (Little et al., 2016) could resolve the implied imbalance,
69 but the extent to which this light output is driven by uptake of isotopically light Zn in the photic
70 zone during photosynthesis versus diagenetic fixation of light Zn in sulfide within the sediment
71 is currently debated (Little et al., 2016; Vance et al., 2016a).

72 The variability that has been observed to date in the dissolved pool is confined to the upper ocean,
73 consistent with biological cycling exerting an important control on oceanic Zn isotopes.
74 However, within the surface ocean, an important difference has emerged. In the low latitude
75 Atlantic, Zn isotopes show a shift towards lighter values in waters of the upper ocean (Conway

76 and John, 2014a). By contrast, the surface Southern Ocean shows remarkably constant Zn isotope
77 compositions (Zhao et al., 2014; Archer et al., 2016). This homogeneity in Zn occurs despite the
78 fact that dissolved Zn concentrations drop by about a factor of 40 moving away from the
79 upwelling zone in the Antarctic zone of the Southern Ocean, as water is rapidly depleted in
80 nutrients in the Ekman flow northwards to the sub-Antarctic (Wyatt et al., 2014; Zhao et al.,
81 2014).

82 There are a number of factors that might explain this important difference between the Southern
83 Ocean and other parts of the global ocean. The first is that the ecology of the Southern Ocean is
84 dominated by fast-growing diatoms (*e.g.* Armbrust, 2009). Marine diatoms not only account for
85 as much as 40 % of oceanic CO₂ fixation (Armbrust et al., 2004), but also appear to be responsible
86 for more than half of export production, that portion of primary production that escapes recycling
87 in the photic zone (Smetacek et al., 2012). Given that Southern Ocean diatoms exhibit
88 particularly high cellular Zn contents, with phosphate-normalized Zn abundances that are up to
89 a factor of 10 higher than average oceanic phytoplankton (Twining and Baines, 2013), this region
90 and these organisms must be key to the isotopic character of the biogenic output of Zn to sediment
91 (Vance et al., 2017).

92 Other features of the Southern Ocean are potentially relevant here. Over most of the photic zone
93 of the global oceans, Zn in seawater solutions is predominantly complexed by organic ligands,
94 with only a small fraction of the dissolved pool existing as the bioavailable Zn²⁺ species (*e.g.*
95 Bruland, 1989; Donat and Bruland, 1990; Ellwood and Van den Berg, 2000; Ellwood, 2004;
96 Lohan et al., 2005). The Southern Ocean is the only location as yet known where total dissolved
97 Zn is in excess of the ligand concentration, so that the bioavailable Zn²⁺ concentration is high
98 (Baars and Croot, 2011). Moreover, chronic Fe-limitation in the Southern Ocean might exert a
99 key control that not only limits diatom growth, but might also affect the Zn uptake physiology of
100 diatoms.

101 The aim of this contribution is to explore these issues using a culturing approach. In particular,
102 we seek to investigate the reasons why diatoms in the Fe-limited Southern Ocean display their

103 distinctive characteristics in terms of uptake stoichiometry and Zn isotope systematics. To our
104 knowledge, *Thalassiosira oceanica* is thus far the only marine diatom for which Zn isotope
105 behavior during uptake has been studied (John et al., 2007), though there is a significant amount
106 of information on the processes controlling *elemental* uptake patterns (see Section 2). Important
107 environmental factors that may be relevant in the real ocean, such as, for example, the impact of
108 external growth limiting factors such as low Fe concentrations, have not been explored.
109 Specifically, here, we document Zn isotope systematics during uptake for another diatom species.
110 Secondly, we seek to elucidate the physiological interplay between Zn and Fe uptake with respect
111 to the distribution of Zn isotopes during uptake into cultured marine diatoms of two different
112 species. Third, we aim to set the isotopic data in the context of variation in cellular Zn quotas,
113 with particular emphasis on the variability of Zn/P ratios with decreasing Fe concentrations.

114 **2. Background**

115 The processes controlling uptake of micronutrient metals by phytoplankton have been studied in
116 culture for three decades (*e.g.* Morel et al., 1979; Sunda and Huntsman, 1992, 1995b, 1997; Lis
117 et al., 2015), and this work serves as a launching pad for the stable isotope work detailed in this
118 contribution. It has long been known that the uptake of metals such as Fe by marine
119 phytoplankton is controlled by the availability of an inorganically bound, unchelated, pool,
120 denoted Fe' (Sunda and Huntsman, 1997; Shaked et al., 2005; Shaked and Lis, 2012). In culturing
121 experiments, this bioavailable pool of all non-organically bound 'free metals' is commonly kept
122 at constant and low levels over the duration of the experiments using a transition metal buffer,
123 typically strong organic chelators (Anderson and Morel, 1982; Sunda et al., 2005). The fact that
124 the relationship between Fe' and uptake rate holds only for surface area normalized rates (Sunda
125 and Huntsman, 1995b, 1997; Lis et al., 2015) suggests that diatoms regulate their Fe uptake *e.g.*
126 by modifying the number of transport proteins actively carrying metals across the cell wall. The
127 light-induced dissociation of the Fe-EDTA complex (Sunda and Huntsman, 2003) and an
128 extracellular Fe reduction step (Shaked et al., 2005) are further important influences on Fe uptake
129 rates in culture.

130 In the case of Zn, available knowledge goes beyond the simple observation that uptake rates
131 correlate with the bioavailable Zn' concentration. There is, for instance, evidence for at least two
132 different uptake mechanisms, high- and low-affinity pathways (Sunda and Huntsman, 1992),
133 previously suggested to cause different isotope effects (John et al., 2007). Whereas the first is
134 active over the entire range of naturally occurring bioavailable Zn concentrations, an additional
135 mechanism, which becomes active at Zn levels above the saturation level of the first pathway,
136 may be able to further increase uptake. Previous research has also suggested that the binding rate
137 to cell wall transporters is related to the water loss rate for the reacting aqueous species, and is
138 thus largely independent of the chemical nature of the membrane transporter site (Hudson and
139 Morel, 1990; Hudson, 1998; Sunda and Huntsman, 1998). In other words, the rate-limiting step
140 in the entire Zn uptake kinetics, from the transition metal buffer to the inside of the diatom, is the
141 formation of an inner-sphere from an outer-sphere complex at the membrane transporter (Figure
142 1). Although such rate constants are important for marine life, their numerical values have not
143 usually been measured, but theoretically predicted (Hudson and Morel, 1990). Stable metal
144 isotopes offer an opportunity to quantitatively explore the molecular basis behind such uptake
145 mechanisms.

146 **3. Materials & Methods**

147 Only ultrapure water, with a conductivity of 18.2 M Ω ·cm, was used in this study and came from
148 a Milli-Q[®] integral water purification system (Merck, Millipore, Germany). Reagent grade acids
149 were twice purified by sub-boiling distillation (DST-1000, Savillex, USA). All salts used for the
150 preparation of artificial seawater solutions were either of trace metal purity, or solutions made
151 from them were cleaned using a chelating resin (Chelex[®] 100, Bio-Rad, USA). Handling of all
152 reagents, solutions, and phytoplankton cultures was carried out under 'Class 100' clean
153 laboratory conditions at constant humidity of around 10 % and a temperature of 21.2 $\pm$ 0.2 °C.

154 3.1 Artificial seawater medium

155 The artificial medium used in this study was designed to allow variation of the bioavailable Fe'
156 concentration from conditions that yield maximum growth of the studied organism down to those
157 that significantly limit growth. The maximum inorganic Fe (Fe') concentration used was high
158 enough to achieve intense growth and low enough to avoid the precipitation of extra Fe onto
159 diatom surfaces (Sunda and Huntsman, 1995b, 1997). Since the principle aim here is to
160 investigate the variation in Zn uptake and isotope fractionation as a function of bioavailable Fe,
161 the bioavailable Zn concentration was kept constant.

162 The culture medium we use here is similar to a medium whose history has previously been
163 reviewed by Berges et al. (2001). The seawater base, however, has been adjusted to a final salinity
164 of $35.93 \pm 0.01 \text{ g kg}^{-1}$ with NaCl. Whereas the concentrations of nitrate, phosphate, and all
165 vitamin supplements follow these authors, silicate was kept at a slightly lower level according to
166 Provasoli (1968). The trace elements manganese (Mn), molybdenum (Mo), and selenium (Se)
167 were also adjusted to the values given by Berges et al. (2001), in contrast to cobalt (Co) whose
168 concentration follows Harrison et al. (1980).

169 The most important characteristics of the medium for the purposes of this study relate to the
170 concentrations of the metals Fe, Ni, and Zn. Whereas Fe' was varied in the range between 5.6
171 and $111.5 \text{ pmol l}^{-1}$, the inorganically bound (Me') and free divalent (Me^{2+}) concentrations of the
172 two other metals (Me) have been kept constant. Ni was kept at low levels of 2.33 ± 0.02 and 1.31
173 $\pm 0.01 \text{ pmol l}^{-1}$ (2 SD, n=18) and Zn at elevated concentrations of 158.8 ± 0.9 and 104.9 ± 0.6
174 pmol l^{-1} (2 SD, n=18), of Me' and Me^{2+} respectively. Copper (Cu), which was not present in the
175 previously described recipe, has been added as a hydrated sulfate salt at a final total concentration
176 of 40 nmol l^{-1} . This translates to bioavailable Cu' and Cu^{2+} concentrations as low as ~ 0.5 and
177 $< 0.05 \text{ pmol l}^{-1}$ (n=18). Aqueous speciation has been calculated according to Sunda et al. (2005)
178 and references therein.

179 This medium contrasts with that previously used by John et al. (2007) mainly in its Fe
180 concentration, which here was kept several orders of magnitude lower. The rationale for this

181 modification is further outlined in Section 3.3. The chosen bioavailable Zn level was such that
182 uptake is dominated by the high-affinity pathway (Sunda and Huntsman, 1992), with only a small
183 contribution via low-affinity uptake. The resulting choice of a fairly high Zn concentration, close
184 to where low-affinity uptake also starts to become important, is a compromise between the
185 attempt to avoid a second active mechanism and the necessity to incorporate a minimum Zn quota
186 to allow isotope analysis (see Appendix).

187 **3.2 Diatom strains and culturing techniques**

188 Two different diatom strains were obtained from the National Center for Marine Algae and
189 Microbiota (NCMA), formerly known as Provasoli-Guillard Center for Culture of Marine
190 Phytoplankton (CCMP), Bigelow Laboratories, USA. Both strains were obtained and kept axenic
191 by handling them using sterile techniques. These two strains were chosen as both originate in the
192 open ocean oligotrophic surface waters of the Sargasso Sea, North Atlantic. In this study we
193 compare the extensively studied diatom *Thalassiosira oceanica* (CCMP 1005), with a less well-
194 known representative of the genus *Chaetoceros* (CCMP 199).

195 Light was supplied to phytoplankton cultures in 15- to 9-hour day to night cycles at a constant
196 photon flux density of $40 \mu\text{mol m}^{-2} \text{s}^{-1}$, as mapped with a spherical quantum sensor LI-193 (LI-
197 COR®, Nebraska, USA). All cultures were acclimated to the given light intensity and to low Fe
198 concentrations, for at least 5 transfer cycles. Cell numbers were quantified using light microscopy
199 and a Reichert Bright-Line hemocytometer (Hausser Scientific, USA) with a Neubauer ruling, in
200 which volumes of typically $0.1 \mu\text{l}$ were counted. Counting results were routinely complemented
201 with Coulter counter cell numbers and volumes. The specific growth rate, μ , was determined by
202 linear regression of the natural logarithm of cell counts in time versus cell number plots. Sterile
203 techniques were used whenever diatom cultures or media solutions were handled. Diatom cells
204 were separated from their residual culturing medium by $0.2 \mu\text{m}$ membrane filtration, using pre-
205 cleaned vertical twin-membrane centrifugal concentrators (Vivaspin 20, Sartorius, Germany).
206 Media remnants were washed off the collected biomass with UV-treated equatorial Atlantic
207 seawater, with notably low Zn in the range of $0.01\text{-}0.05 \text{ nmol kg}^{-1}$ (Zhao, 2011).

208 3.3 Fe-hydroxides removal from diatom surfaces

209 All diatoms cultured in this study were washed only with metal-free equatorial Atlantic seawater.
210 Cultured marine diatoms bear the potential to precipitate Fe-hydroxides on their surface and Zn
211 has a generally high propensity to adsorb onto such Fe-phases. Considering the strong affinity of
212 heavy Zn for Fe-hydroxides (Pokrovsky et al., 2005), their presence could affect the Zn isotope
213 composition of the bulk biomass. Surface treatments that first remove Fe-hydroxides (Tovar-
214 Sanchez et al., 2003) have thus been considered essential to obtain cellular Zn contents or Zn
215 isotope compositions (John et al., 2007). John et al. (2007) speculate that the potential problem
216 of surface Fe-oxides could be avoided by simply lowering the total Fe concentration in the
217 culturing medium Here we briefly summarize arguments in favor of a simple seawater wash.

218 Much of what is known about intracellular Zn quotas and Zn uptake rates originates from early
219 culturing work consistently conducted by washing cells only with seawater (Sunda and
220 Huntsman, 1992; Ellwood and Hunter, 2000). More recently, it has become possible to image
221 intracellular metal contents and to clearly separate these from surface-associated fractions,
222 through methods such as synchrotron based X-ray fluorescence imaging techniques (Twining et
223 al., 2003). The metal quotas found in early culturing work (*c.f.* Sunda and Huntsman, 1992;
224 Twining et al., 2003) agree well with these found with these in-situ methods, for the same
225 *Thalassiosira* strain, indicating that seawater washes indeed obtain accurate intracellular Zn
226 concentrations.

227 In previous work, whenever intracellular Fe quotas or Fe uptake rates have been the focus,
228 surface-bound Fe-hydroxides were carefully dissolved (Hudson and Morel, 1989; Sunda and
229 Huntsman, 1995b). The Fe uptake rates obtained in this study, presented later and all attained
230 without any dissolution of solid Fe-phases, are in good agreement with those previously reported
231 (Sunda and Huntsman, 1995b, 1997). We interpret this observation as further evidence for the
232 fact that the total Fe concentrations in the culturing media were sufficiently low to avoid the
233 precipitation of Fe-hydroxides. Six additional cultures per strain were deliberately grown at
234 increased Fe' levels to yield surface precipitates by design (Table 1).

235 Tang and Morel (2006) extensively studied the impact of large quantities of surface-bound Fe-
236 hydroxides on the distribution of other transition metals associated with diatom biomass. The P
237 normalized Zn quotas they obtained with NaCl washed diatoms were almost identical, over the
238 entire observed range of Fe-precipitates, with those obtained from experiments in which surface-
239 bound Fe-hydroxides were carefully dissolved. In particular, at low total Fe concentrations, both
240 methods gave identical results. The authors suggest that, under most circumstances, one obtains
241 accurate cellular Zn concentrations just by the removal of media remnants (Tang and Morel,
242 2006).

243 John et al. (2007) found that unwashed diatom cells, cultured at the bioavailable Zn
244 concentrations used here, were ~0.6 ‰ heavier than biomass samples from which surface-bound
245 Fe, and possibly co-precipitated Zn, has been removed. These authors also suggest, however, that
246 a simple solution to this problem could be achieved simply by lowering the total Fe concentration,
247 and identified their total medium Fe concentration of 10 $\mu\text{mol l}^{-1}$ as potentially too high to avoid
248 the precipitation of Fe-hydroxides (John and Conway, 2014). If the empirical relationship
249 between total medium Fe concentration and biomass Fe/P ratios (including surface-bound Fe)
250 found by Tang and Morel (2006) for *T. weissflogii* also holds for the *T. oceanica* species cultured
251 by John et al. (2007), then this total medium Fe concentration would imply Fe/P ratios in their
252 biomass $>200 \text{ mmol mol}^{-1}$. As outlined later, the present study finds mean Fe/P ratios for *T.*
253 *oceanica* of $1.8 \text{ mmol mol}^{-1}$, at least a factor of 100 lower. Hence, we argue that the previously
254 determined impact of surface-bound Fe-hydroxides is not significant for the present study.

255 **3.4 Elemental and stable isotope analysis**

256 All biomass samples were re-suspended in pre-cleaned NaCl solutions adjusted to the same
257 osmolality found within diatom cells, to prevent cell lysis. The resulting cell suspensions were
258 pipetted out of the centrifugal concentrator (*c.f.*, previous section) and were dried down before
259 digestion in double distilled 65% HNO_3 at 120 °C for 16 hours. All experimental solutions were
260 re-dissolved in 2 % HNO_3 for elemental and isotopic analysis, after a final dry-down.

261 The procedures used for elemental and stable isotope analysis are very similar to those in
 262 previous publications from this laboratory (Little et al., 2016; Vance et al., 2016a; Vance et al.,
 263 2016b). In brief, a ThermoScientific Element XRTM inductively-coupled plasma mass
 264 spectrometer (ICP-MS) was used for elemental analysis, and all isotope analyses were performed
 265 on a Neptune PlusTM multiple-collector inductively-coupled plasma mass spectrometer (MC-
 266 ICP-MS) of the same manufacturer. Sample purification for isotope analysis was done by anion
 267 exchange chromatography (Maréchal et al., 1999; Archer and Vance, 2004; Bermin et al., 2006).
 268 Mass fractionation occurring during ion exchange chromatography or associated with the mass
 269 spectrometer itself was corrected by using the double-spike approach as described by Bermin et
 270 al. (2006) and Zhao et al. (2014), in combination with a data reduction scheme presented by
 271 Siebert et al. (2001). The data presented here are given in the standard delta notation, in per mil,
 272 reported relative to JMC 3-0749 (Maréchal et al., 1999): $\delta^{66}\text{Zn} (\text{‰}) = [({}^{66}\text{Zn}/{}^{64}\text{Zn})_{\text{sample}} /$
 273 $({}^{66}\text{Zn}/{}^{64}\text{Zn})_{\text{JMC 3-0749}}] - 1$. Accuracy and precision were monitored relative to a secondary
 274 standard, IRMM-3702, previously reported to yield a value of +0.32 ‰ (Ponzevera et al., 2006;
 275 Cloquet et al., 2008), recently corrected to a value of +0.30 ‰ (Moynier et al., 2017). Relative
 276 to JMC-Lyon, we obtain $\delta^{66}\text{Zn} = 0.30 \pm 0.06 \text{ ‰}$ (2 SD, n = 163 over 380 days).

277 All our culturing results are reported as the fractionation observed between the medium and the
 278 separated biomass, here denoted $\Delta^{66}\text{Zn}_{\text{biomass} - \text{medium}} (\text{‰}) = \delta^{66}\text{Zn}_{\text{biomass}} - \delta^{66}\text{Zn}_{\text{medium}}$. All diagrams
 279 plot the external precision, based on replicate analyses of IRMM-3702 as noted above, except
 280 when internal errors on individual samples exceed long-term external reproducibility.

281 **4. Results**

282 The new Zn and Fe data presented here (Table 1) allow comparison of two distinct open ocean
 283 diatoms, both originating from the same oligotrophic surface waters of the Sargasso Sea, North
 284 Atlantic. Whereas *T. oceanica* (Hasle, 1983) has been extensively studied, little is known about
 285 the representative of the genus *Chaetoceros* studied here. The mean cellular volume of the two
 286 strains was found to be very similar, at 305 μm^3 for *T. oceanica* and 315 μm^3 for *Chaetoceros*.
 287 In contrast to *T. oceanica* cells, the volumes of *Chaetoceros* sp. decrease systematically with

288 lower medium Fe', through the range 256 to 350 μm^3 . This finding conforms with theoretical
289 predictions by Hudson and Morel (1990), suggesting that small cells are favored under Fe-
290 limiting conditions.

291 **4.1 Growth suppression due to Fe' limitation**

292 Both diatom strains reach specific growth rates of about 0.85 d^{-1} at Fe' concentrations in the range
293 0.08 to 0.11 nmol l^{-1} . Growth is increasingly limited at lower Fe', but the degree to which this
294 occurs is clearly different for the two species studied. *T. oceanica* is able to maintain a growth
295 rate that is almost half of its initial value (0.41 d^{-1}) at a Fe' level of 0.01 nmol l^{-1} . At this Fe' level
296 *Chaetoceros sp.* suffers growth reduction of 80 %, decreasing to values as low as 0.16 d^{-1} (Figure
297 2A). Growth suppression has thus been achieved by applying an external forcing, namely Fe'
298 limitation. Surface area-normalized Fe uptake rates decrease, for both studied species, with
299 decreasing Fe' concentrations made available to the diatom cell (Figure 2B). All Fe uptake rates
300 reported in this study agree well with those previously reported for Fe'-limited diatom cultures
301 by Sunda and Huntsman (1997).

302 **4.2 Zn uptake rates and the distribution of Zn isotopes**

303 Mean biomass associated Zn quotas, here reported for *T. oceanica* and *Chaetoceros sp.*, are in
304 good agreement with those previously obtained for three different *Thalassiosira* strains (Sunda
305 and Huntsman, 1992). The variability in Zn/C, however, is higher than previously reported,
306 spanning a range between 7.4 and 25 $\mu\text{mol mol}^{-1}$ (blue whisker in Figure 3A). It is shown later
307 that this variation in Zn/C is correlated with Fe' (Table 1).

308 For *Chaetoceros sp.* surface area normalized Zn uptake rates were found to be in the range of 8.4
309 to 46.9 $\text{nmol m}^{-2} \text{d}^{-1}$. Those of *T. oceanica*, in contrast, were higher and consistently exceeded
310 values of 45.2 $\text{nmol m}^{-2} \text{d}^{-1}$, with the exception of a single aberrant value at 28.9 $\text{nmol m}^{-2} \text{d}^{-1}$.
311 Moreover, Zn uptake rates of *Chaetoceros sp.* decreased linearly with increasingly suppressed
312 growth. Those of *T. oceanica*, in contrast, decrease with a similar slope from their maximum

313 value to a specific growth rate of $\sim 0.6 \text{ d}^{-1}$, after which the slope of growth inhibition becomes
314 steeper (Figure 3B).

315 With respect to the bulk culturing medium, the *T. oceanica* biomass was slightly preferentially
316 enriched in light Zn isotopes, yielding a mean $\Delta^{66}\text{Zn}_{\text{biomass} - \text{medium}}$ signature of $-0.13 \pm 0.11 \text{ ‰}$ that
317 is constant across a wide range of generally high Zn uptake rates. The Zn isotope fractionation
318 upon uptake is thus in the same direction as, but smaller than that found by, John et al. (2007), at
319 $\Delta^{66}\text{Zn}_{\text{biomass} - \text{medium}} = -0.41 \pm 0.09 \text{ ‰}$, for the same species at similar free Zn levels. It is within
320 uncertainty of that found by John et al. (2007) at free Zn concentrations a factor of 5 lower. In
321 contrast, comparatively low Zn uptake rates obtained with *Chaetoceros sp.* correlate with $\Delta^{66}\text{Zn}$
322 $\text{biomass} - \text{medium}$ fractionations that range from values as low as $-0.42 \pm 0.06 \text{ ‰}$ up to $+0.85 \pm 0.14$
323 ‰ , the latter at the lowest Zn uptake rates (Figure 3C).

324 4.3 Physiological interplay between Zn and Fe

325 The cellular Zn uptake rates of both studied diatom species are correlated with those of Fe, even
326 though the absolute rates of *Chaetoceros sp.* are only about half those of *T. oceanica* (Figure 4).
327 Given that cellular Zn uptake is a function of the specific growth rate (Figure 3B), which is again
328 set by an external forcing, namely Fe' (Figure 2A), it is valid to also explore Zn uptake
329 dependence on Fe' (Figure 5).

330 The bioavailable Zn concentration was deliberately kept constant in all experiments, to ensure
331 that Fe' is the only variable changed in the system. The P-normalized Zn quota was found to be
332 in the range 0.78 to $2.64 \text{ mmol mol}^{-1}$ under varied degrees of Fe' limitation, equivalent to
333 concentrations from 0.01 to 0.11 nmol l^{-1} (Figure 5A). These numbers are in good agreement
334 with previous culturing work reporting cellular Zn quotas, equivalent to Zn/P ratios in the range
335 1 to 2 mmol mol^{-1} (Sunda and Huntsman, 1992, 1995a; reviewed in Twining and Baines, 2013).
336 A few experiments conducted with Fe' concentrations higher than 0.7 nmol l^{-1} , a threshold above
337 which Fe-hydroxides have previously been documented to occur in culturing solutions (Sunda
338 and Huntsman, 1995b, 1997), gave much higher Zn/P ratios, in the range 4.2 to 5.1 and 3.4 to
339 4.2 for *Chaetoceros sp.* and *T. oceanica*, respectively.

Both diatoms show systematically reduced Zn uptake rates with decreasing levels of Fe' (Figure 5B). The gradient of Zn uptake rates is less steep than those of Fe. *Chaetoceros sp.*, however, whose growth is more severely suppressed relative to that of *T. oceanica*, is also generally characterized by more rapid lowering of Zn uptake rates associated with Fe limitation.

The mean $\Delta^{66}\text{Zn}_{\text{biomass} - \text{medium}}$ of $-0.13 \pm 0.11 \text{ ‰}$ for *T. oceanica* is independent of Fe', similar to the lack of dependence on Zn uptake rates, as described earlier (*c.f.*, Figure 3C). *Chaetoceros sp.*, on the other hand, shows increasingly heavy Zn isotope signatures with decreasing Fe' concentrations (Figure 5C). The most negative $\Delta^{66}\text{Zn}_{\text{biomass} - \text{medium}}$ of $-0.42 \pm 0.04 \text{ ‰}$ observed for *Chaetoceros sp.* were found just below a previously described threshold of $0.7 \text{ nmol l}^{-1} \text{ Fe'}$, above which Fe-precipitates have been described to occur in diatom cultures (Sunda and Huntsman, 1995b, 1997). Six full replicates of diatom strains cultured above this threshold were found to be more variable and to display more positive $\Delta^{66}\text{Zn}_{\text{biomass} - \text{medium}}$ than those cultured at the highest Fe' investigated below this threshold (Figure 5C), consistent with previous findings concerning the impact of surface Fe-hydroxides on Zn isotopes in diatoms (John et al., 2007).

5. Discussion

5.1 Physiological interplay between Zn and Fe

In the set of experiments reported here an external forcing, namely Fe-limitation, has been applied to suppress diatom growth to a variable extent. The physiological interplay between two intracellularly abundant transition metals can thus be studied. The interest in such an analysis originates in the observation that key diatom habitats in the ocean are often Fe-limited (Martin and Fitzwater, 1988; Boyd et al., 2000), but usually not Zn-limited (Moore et al., 2013). A conceptual understanding of these regimes is thus important.

The approach taken here, for the first time, shows how species dependent differences in the degree to which Fe' limits growth (Figure 2A) exerts a control on Zn uptake rates (Figure 5B). In contrast to previous work conducted with coastal diatoms (Sunda and Huntsman, 1997), the open marine species studied here exhibit severe growth limitation due to lower Fe' concentrations

(Figure 2A). Sunda and Huntsman (1997) demonstrated that cell surface area normalized Fe uptake rates of all four coastal species they studied can be described with a single saturation equation for nutrient uptake. Described with a kinetic model analogous to that of Michaelis and Menten (1913), the authors found that saturation was reached at a $V_{\max}$ of $1276 \text{ nmol m}^{-2} \text{ d}^{-1}$ with a K_s of 0.51 nmol l^{-1} . The surface area normalized Fe uptake rates for the oceanic species reported in this contribution can be described with the exact same relationship as for coastal species (Sunda and Huntsman, 1997). We interpret this observation as evidence for the same underlying control *i.e.*, the external forcing from Fe-limitation. On the basis of this finding, the previous relationship can be extended by the two newly characterized oceanic species to yield an updated $V_{\max}$ of $1289 \pm 263 \text{ nmol m}^{-2} \text{ d}^{-1}$ with a corresponding K_s of $0.53 \pm 0.19 \text{ nmol l}^{-1}$ (Table 2).

The Zn uptake rate is similarly positively dependent on Fe' , though the quantitative nature of that dependency is also somewhat different (see the less steep gradients for the data plotted in Figure 5B). There is also apparently a difference between the two organisms studied here. Cause and effect are unclear; it may, for example, be that the more severe suppression of growth in *Chaetoceros* simply reduces the cellular requirement for Zn, a metal that fulfills an important structural function as a cofactor in several essential enzymes (Morel et al., 1994). A prime candidate for an enzyme that might not be needed at reduced growth in the same high quantities as at maximum growth, is the Zn containing carbonic anhydrase (Morel et al., 1994), required for biomass buildup by fixation of atmospheric CO_2 .

The general distribution of Zn isotopes exhibits features as a function of Fe' (Figure 5C) that are analogous to those found for Zn uptake rates (Figure 3C). Whereas *T. oceanica* again shows little variability around a mean $\Delta^{66}\text{Zn}_{\text{biomass} - \text{medium}}$ of $-0.13 \pm 0.11 \text{ ‰}$, *Chaetoceros* cells were found to be increasingly heavy with decreasing Fe' concentrations (Figure 5C). In this context it is important to note again that all these cultures have only been washed with metal-free equatorial Atlantic seawater. To avoid the problem of surface bound Fe hydroxides, the media used here were adjusted to extremely low total Fe concentrations (*c.f.*, Section 3.3). The stronger affinity of heavy Zn for solid Fe-hydroxides (Pokrovsky et al., 2005) would be expected to cause the

393 biomass to be increasingly more fractionated in $\Delta^{66}\text{Zn}$ with increasing quantities of surface bound
394 Fe phases. Contrary to this expectation, the most negative signatures of $-0.42 \pm 0.04 \text{ ‰}$ were
395 observed at the highest Fe', with increasing $\Delta^{66}\text{Zn}_{\text{biomass} - \text{medium}}$ values progressively further away
396 from a previously described threshold of 0.7 nmol l^{-1} , above which Fe-precipitates have been
397 documented to occur in diatom cultures (vertical dashed line in Figure 5; Sunda and Huntsman,
398 1995b, 1997). We tested for the impact of Fe-hydroxides with six full culturing replicates of both
399 strains above the threshold of precipitation, and found the results to be variable. The most
400 negative $\Delta^{66}\text{Zn}_{\text{biomass} - \text{medium}}$ were in good agreement with the numbers observed just below the
401 threshold. Consistent with Pokrovsky et al. (2005), the heaviest fractionation were found to be
402 $+0.18$ to 0.28 ‰ heavier than the most negative (Figure 5C).

403 **5.2 Cellular Zn quotas and Zn/P ratios at low Fe'**

404 The Monod (1949) and Michaelis and Menten (1913) equations are mathematical models that
405 describe phytoplankton growth (Monod) and nutrient uptake (Michaelis-Menten) rates. Both
406 equations, identical in their general form, relate growth rate (μ) and nutrient uptake rate (v) to the
407 nutrient concentration available in an aqueous environment surrounding the cell. In both
408 descriptions, maximum growth (μ_{max}) or saturation of uptake (V_{max}) is reached at high ambient
409 concentrations of a potentially limiting resource, in this case Fe'. The rate of increase in growth
410 or uptake below μ_{max} and V_{max} are conventionally described in terms of empirical half-growth (k)
411 and half-saturation (K_S) constants, defined as the limiting nutrient concentrations at which μ/μ_{max}
412 and v/V_{max} equals 0.5 (see Figure 6).

413 The Droop (1973) equation ($v = \mu Q$) contrasts with the above approaches in that it is the
414 intracellular nutrient quota (Q) that is used to relate growth (μ) and nutrient uptake (v) rates. This
415 treatment accounts for the fact that any organism, even at infinitely low growth rates, will have
416 an internal nutrient quota that is significantly larger than zero. The lower the ambient substrate
417 concentrations, the more the cellular nutrient quota is likely to deviate from what would be
418 expected if the latter is tied only to biomass build-up. In the following we use the Droop

relationship to explore the cellular Zn quotas for known growth and metal uptake kinetics (Figure 6), in order to understand their variability at progressively lower ambient Fe'-levels.

The specific growth rate of *T. oceanica* and *Chaetoceros sp.*, described after Monod (1949) as a function of bioavailable Fe', yield maxima ($\mu_{\max}$) of $0.99 \pm 0.08 \text{ d}^{-1}$ and $0.96 \pm 0.07 \text{ d}^{-1}$ with half saturation constants of $0.021 \pm 0.004 \text{ nmol l}^{-1}$ and $0.009 \pm 0.004 \text{ nmol l}^{-1}$, respectively (Table 2, Figure 6A). A similarly quantitative description of Zn uptake rates was obtained with a pseudo-Michaelis-Menten kinetics (Figure 6B). With the prefix 'pseudo' it is emphasized that the Zn uptake rate is not expressed as a function of the bioavailable Zn concentration as is conventionally done (Michaelis and Menten, 1913), but instead as a function of Fe'. The justification for doing so originates in the results described earlier, showing that Zn uptake rates are coupled to those of Fe (Figure 4), with both dependent on the concentration of Fe' available in the medium (Figure 2B). It is important to note that the set of parameters obtained, *i.e.* a $V_{\max}$ of $58.9 \pm 8.6 \text{ nmol m}^{-2} \text{ d}^{-1}$ and $91.9 \pm 2.2 \text{ nmol m}^{-2} \text{ d}^{-1}$ with half saturation constants of $0.038 \pm 0.013 \text{ nmol l}^{-1}$ and $0.005 \pm 0.001 \text{ nmol l}^{-1} \text{ Fe}'$, for *T. oceanica* and *Chaetoceros sp.*, respectively (Table 2), are not universally valid. Instead, these numbers are specific to a Fe-limitation scenario at the given bioavailable Zn concentration.

The intracellular Zn quota has been suggested to be linked to its uptake rate divided by the specific growth rate of the organism (Droop, 1973). With the aid of the Droop equation and our quantitative descriptions of specific growth rate and Zn uptake as a function of Fe', the cellular Zn quota is seen to change most significantly under Fe limiting conditions (Figure 6C). Cellular Zn quotas can be calculated to decrease by 38 % for the severely Fe limited *Chaetoceros sp.*, while *T. oceanica* cells experience a much smaller change, with Zn increasing by 7.6 % at the lowest Fe'.

Droop quotas can furthermore help to elucidate the physiological peculiarities of the two distinct diatom strains when exposed to identical environmental constraints. *T. oceanica* can sustain high reproduction rates, even if Fe gets to low concentrations, and must contain an effective resource-acquisition machinery to ensure consistently high cellular Zn quotas. *Chaetoceros sp.*, in contrast,

446 is best adapted for exponential growth in Fe-rich waters, but suffers from low Fe' concentrations,
447 at levels that do not affect *T. oceanica*. In contrast to *T. oceanica*, the growth rates of *Chaetoceros*
448 *sp.* are considerably lower at reduced Fe' levels. A lower expression of growth-related enzymes
449 is required to sustain the observed reproduction rates. In other words, at high Fe', *Chaetoceros*
450 holds a high proportion of growth machinery, significantly reduced when growth becomes
451 limited.

452 5.3 Zn uptake rates and Zn isotope fractionation upon uptake

453 The new Zn stable isotope data presented here have two principal features. Firstly, a species
454 whose growth is less affected by low Fe', *T. oceanica* (Figure 2A), is able to maintain relatively
455 high Zn uptake rates (Figure 3B), with a nearly constant and slightly negative (-0.02 to
456 -0.19 ‰) fractionation of $\Delta^{66}\text{Zn}_{\text{biomass} - \text{medium}}$ (Figure 3C). Secondly, the species whose growth is
457 severely Fe-limited, the representative of the genus *Chaetoceros* studied here, shows more
458 variable biomass Zn isotope signatures at a generally low Zn uptake rate (Figure 3B and C). For
459 Zn uptake rates at the higher end of the range for *Chaetoceros*, those that overlap with those of
460 *T. oceanica*, *Chaetoceros* also shows small negative $\Delta^{66}\text{Zn}_{\text{biomass} - \text{medium}}$. But at the lower uptake
461 rates that occur at low Fe', it records variably positive $\Delta^{66}\text{Zn}_{\text{biomass} - \text{medium}}$, up to +0.85 ‰.

462 With regard to the first of these observations, it is theoretically possible that that faster diffusion
463 of light isotopes (Rodushkin et al., 2004) through the medium could contribute to the enrichment
464 of light Zn isotopes within the phytoplankton cell, but in none of these experiments would
465 transport to the cell have been diffusion limited. In fact, the constant and slightly negative
466 fractionation for *T. oceanica* is consistent with negligible fractionation upon uptake, given the
467 presence of EDTA as a transition metal buffer in the culturing medium. Previous experiments
468 studying the equilibrium fractionation between chelating resins and free Zn found heavy Zn
469 isotopes preferentially associated with this ligand. The corresponding enrichment of light
470 isotopes in the non-chelated Zn pool is consequently in the range of -0.16 to -0.33 ‰ (Ban et al.,
471 2002; Ding et al., 2010a; Ding et al., 2010b; Markovic et al., 2017). As it is the free divalent
472 metal that is bioavailable (Anderson et al., 1978; Anderson and Morel, 1982; Hudson, 1998),

473 diatom extract Zn from a pool that is significantly lighter than an equilibrated bulk medium, used
474 as a reference to calculate the fractionation upon uptake into cells. A biomass sample such as *T.*
475 *oceanica*, here consistently found to show fractionations ($\Delta^{66}\text{Zn}_{\text{biomass} - \text{medium}}$) of around -0.13 ‰,
476 might consequently only reflect the aqueous equilibrium between the bioavailable free Zn and
477 EDTA in the culturing medium, potentially implying no fractionation at all associated with Zn
478 uptake, an interpretation that has previously been put forward for similar culturing results by
479 John et al. (2007).

480 *A priori*, the second observation could be explained in two different, though perhaps related,
481 ways. One possible explanation of the heavy isotope signatures seen in *Chaetoceros sp.* at low
482 Zn uptake rates could relate to the more severe growth limitation seen for this species at low Fe'.
483 Previous researchers have shown that molecules such as saccharides can enhance the
484 bioavailability of Fe to marine phytoplankton (Hassler et al., 2011), including diatoms belonging
485 to the genus *Chaetoceros* (Hassler et al., 2011; Raposo et al., 2013). The release of surface-bound
486 organics is a survival strategy to scavenge Fe, which progressively becomes scarcer under the
487 environmental conditions studied here. Such saccharides almost certainly scavenge heavy Zn
488 (Coutaud et al., 2014). Thus, increasing amounts of such extracellular polymeric substances
489 (EPS) excreted with decreasing Fe' might represent a possible explanation for the observed heavy
490 Zn isotope signatures. Alternatively, Zn associated with EPS could simply have greater relative
491 importance at the decreased quantities of Zn that are internalized at low Fe'. We are not aware of
492 any published work on EPS associated with *T. oceanica*, but this does not mean that the diatom
493 is unable to exude such components. Whether EPS could cause such heavy $\Delta^{66}\text{Zn}_{\text{biomass} - \text{medium}}$ is
494 highly speculative at this stage and awaits further investigation, ideally directly comparing the
495 two diatom strains.

496 The second possible explanation is a switch from a kinetic control of Zn uptake at high uptake
497 rates to an equilibrium control as uptake rate declines. In the following, the term 'kinetic isotope
498 effect' refers to all those effects that cause the fractionation of stable Zn isotopes associated with
499 incomplete and unidirectional processes, such as those typical for dissociation or biologically

500 mediated chemical reactions. There is a distinct threshold in the variation of biomass Zn isotope
501 signatures as a function of Zn uptake rate, with $\Delta^{66}\text{Zn}_{\text{biomass} - \text{medium}}$ increasing sharply at a surface
502 area normalized uptake rate below $35 \pm 10 \text{ nmol m}^{-2} \text{ d}^{-1}$. If the dehydration of the hexa-aquo Zn
503 to form an inner-sphere surface complex at the transporter site (Figure 1) is the rate limiting step
504 in the uptake kinetics (Hudson and Morel, 1990; Hudson, 1998; Sunda and Huntsman, 1998),
505 light isotopes would undergo this transformation slightly faster than heavy Zn (Bigeleisen and
506 Wolfsberg, 1958; and references therein). Zn uptake may be entirely under kinetic control above
507 this threshold (Figure 7A), a situation in which every transport enzyme runs at its maximum
508 turnover. This is supported by the fact that once the observed maximum preference for light
509 isotopes is achieved, it remains constant. The cell can still increase the number of enzymes per
510 unit area of cell wall to further facilitate higher Zn uptake rates, but the dehydration at individual
511 transporter sites would remain constant, and governs the maximum achievable preference for
512 lighter Zn isotopes (Figure 7B).

513 If the cellular Zn uptake rate is down-regulated to values lower than the dehydration rate of the
514 Zn hexa-aquo complex, the kinetically controlled preference for light isotopes at the transporter
515 site would become progressively less dominant (Figure 7C). In our experiments, the observed
516 fractionation ($\Delta^{66}\text{Zn}_{\text{biomass} - \text{medium}}$) becomes increasingly positive with lower Zn uptake rates.
517 Given the strength of bonds between Zn and many organic ligands, isotopically heavier biomass
518 signatures at low uptake rates are consistent with an increasing equilibrium component
519 (Bigeleisen and Mayer, 1947; Schauble, 2004; Fujii et al., 2014), and this has been observed
520 experimentally for Zn (Jouvin et al., 2009). It is currently not entirely clear whether Zn uptake
521 can be low enough that conditions close to thermodynamic equilibrium start to become relevant.
522 The sharp increase in $\Delta^{66}\text{Zn}_{\text{biomass} - \text{medium}}$ is thus interpreted as a continuum that is likely to develop
523 towards equilibrium, but in any case away from a purely kinetically controlled system.

524 One could postulate that the data in Figure 3C represent a single relationship for both species. In
525 this case, and consistent with the above explanation of heavy versus light Zn isotopes, it is Zn
526 uptake rate itself that is the key controlling variable for biomass Zn isotope signatures. In this

view, *T. oceanica* never shows heavy isotope signatures because it exhibits Zn uptake rates that are mostly higher than the threshold around $35 \text{ nmol m}^{-2} \text{ d}^{-1}$, even at the lowest Fe' . Alternatively, both diatoms might follow their individual pattern. In this view, however, *Chaetoceros sp.* never reaches Zn uptake rates high enough to achieve a constant preference for light isotopes. Even though this view is currently only poorly supported by the available data, this would imply species-dependent differences in the maximum preference for light Zn isotopes. Such an observation, in consequence, suggests structural differences in the active site of the transporter proteins or two different uptake mechanisms.

6. Concluding remarks: implications for oceanic Zn isotopes

An important finding of the experiments documented here is that the extent to which growth is limited by an external forcing, such as Fe' , controls the pace of Zn uptake (Figure 7D). If reduced Zn uptake is a physiological response to lower cellular Zn demands, it seems likely that other external forcings might cause a similar down-regulation of the Zn uptake rate, as an indirect consequence of growth suppression.

These results potentially have important implications for the interpretation of the global oceanic distribution of Zn and its isotopes, though there are also open questions that require further experimentation. In terms of the global surface ocean, the Southern Ocean has already been noted to be unusual. Here diatoms dominate Zn cycling (Vance et al., 2017), and the lack of Zn isotope fractionation in the dissolved pool across a 40-fold drop in concentration as diatoms deplete it (Wyatt et al., 2014; Zhao et al., 2014; Vance et al., 2017) suggests a lack of fractionation upon uptake. The fact that this lack of isotope fractionation occurs in a region with severe Fe limitation is, at first sight, somewhat at odds with the experimental findings here. On the other hand, where Fe is supplied to the Southern Ocean, diatoms grow extremely rapidly, in blooms (Boyd et al., 2000). Another key feature of the Southern Ocean is that it is the only known surface ocean location where total Zn concentrations far outstrip those of the complexing organic ligands, leading to very high bioavailable free Zn ions (Baars and Croot, 2011). This has two impacts. First, Zn uptake rates will be rapid in response, both to high bioavailable Zn (this study, Sunda

554 and Huntsman, 1992) and to a diatom ecology that is characterized by fast growing blooms in
555 the Southern Ocean. Second, if a substantial portion of the total Zn pool is represented by free
556 Zn, then the isotopic composition of the latter pool will be close to the bulk dissolved pool itself.
557 In this case, the lack of fractionation during uptake may simply suggest that Zn uptake is under
558 kinetic control.

559 Much of the low latitude upper Atlantic Ocean appears to exhibit light Zn isotope compositions
560 in the dissolved pool (Conway and John, 2014a). Zhao et al. (2011; 2014) suggest that light sub-
561 surface Zn isotopes might be driven by very shallow regeneration of a light cellular signature
562 created in the photic zone immediately above. In terms of the experimental data presented here,
563 the light biomass signature could derive from a very small free Zn pool, which outside the
564 Southern Ocean is tiny relative to the organically complexed pool and must be isotopically light
565 relative to the total dissolved reservoir (Ban et al., 2002; Jouvin et al., 2009; Ding et al., 2010a;
566 Ding et al., 2010b; Markovic et al., 2017), again without fractionation upon uptake. John and
567 Conway (2014), on the other hand, favor scavenging of heavy isotopes onto organic matter,
568 creating an isotopically light residual pool, as a possible explanation for a light upper ocean. It is
569 also interesting that the most severely Fe-limited *Chaetoceros* cultures, with the lowest Zn uptake
570 rates, show the heaviest Zn isotope signatures. The findings here allow consideration of another
571 potential driver: residual light signatures in the surface ocean could be driven by preferential
572 uptake of the heavy isotope at very slow rates of Zn uptake.

573 **Appendix**

574 The data re-evaluated in this appendix originates in Sunda and Huntsman (1992). The previous
575 dataset was re-evaluated to more precisely identify the highest bioavailable Zn^{2+} concentration
576 that is still likely to be explained by a single, high-affinity, uptake mechanism alone (Figure A.1),
577 which is important for the experiments in this paper because we needed to identify the highest
578 Zn^{2+} concentration that could be used without introducing the further complication of two uptake
579 mechanisms.

580 This question was addressed by assuming that high-affinity uptake can be described by the
581 Michaelis-Menten equation. Furthermore, it was assumed that any additionally active
582 mechanism, that is able to further increase uptake above the maximum of high-affinity uptake,
583 would negatively impact a Michaelis-Menten curve fit. The previously reported dataset was
584 incrementally explored by changing the number of samples in the evaluation scheme (Figure
585 A.2). Zn/C ratios recorded at the lowest Zn^{2+} concentrations were always included in the
586 calculated curve fits. Ratios obtained at the highest Zn^{2+} were incrementally taken out of the
587 analysis. Datasets from the minimum up to Zn^{2+} concentrations of ~ 100 , 10, 1, 0.3, and 0.1 nmol l^{-1}
588 l^{-1} were evaluated in the given order. The root mean squared error (RMSE) of the Michaelis-
589 Menten equation has been used as the evaluation criterion to assess the goodness of fit. The
590 dataset was assumed to be adequately described by the Michaelis-Menten fit corresponding to a
591 single, high-affinity, uptake mechanism when the root mean squared error (RMSE) falls below a
592 numerical value of 10, here considered a reliable measure for the accuracy of the fit
593 (Supplementary Figure 2C and D). More conservative estimates would set a RMSE threshold of
594 7.5 (Supplementary Figure 2E and F). The following root mean squared errors were achieved for
595 the above listed Zn^{2+} concentrations: 630.4, 17.2, 10.94, 7.75, and 6.49 (Supplementary Figure
596 2). On the basis of this analysis Zn^{2+} concentrations up to 0.1 nmol l^{-1} , perhaps up to 0.3 nmol l^{-1}
597 l^{-1} , can be explained with a single Zn uptake mechanism. Up to this concentration, uptake is likely
598 to be dominated by high-affinity pathways with only a marginal contribution of an additionally
599 active low-affinity pathway. Given this result, a Zn^{2+} concentration of 0.1 nmol l^{-1} was used here.

600 **Acknowledgements**

601 We are grateful to Alysia D. Cox for help with setting up a phytoplankton culturing lab at ETH
602 Zurich and to Timothy I. Eglinton for allowing us access to biology laboratories and incubator
603 facilities. We also wish to thank Corey Archer for valuable support with elemental and isotopic
604 analysis and Amélie Ritscher for her work as a research assistant at ETH Zurich. Finally we thank
605 Susan Little for constructive feedback on a previous manuscript of this paper, Laura Wasylenki
606 and an anonymous reviewer for constructive reviews, and Claudine Stirling for efficient editorial

607 [handling](#). Financial support was provided by ETH and the Swiss National Science Foundation
608 (SNF) through grant 200021-143262.

914

915 **Figure captions**

916 **Table 1.** Measured Fe and Zn uptake rates, cellular Zn quotas, and Zn isotope results ($\Delta^{66}\text{Zn}$
 917 $\text{biomass} - \text{medium} = \delta^{66}\text{Zn}_{\text{biomass}} - \delta^{66}\text{Zn}_{\text{medium}}$) obtained for two different cultured marine diatoms. The
 918 specific growth rate (μ) has been suppressed to a different extent by the systematic variation of
 919 Fe' at constant bioavailable Zn levels.

920 **Table 2.** Results of all non-linear Monod (1949), Michaelis-Menten (1913), and pseudo-
 921 Michaelis-Menten curve fits. The prefix 'pseudo' refers to the fact that the Michaelis-Menten
 922 equation is used to describe the Zn uptake rate as a function of Fe', rather than the Fe uptake rate
 923 (*c.f.*, Figure 6). The superscript * refers to a previous fit result by Sunda and Huntsman (1997),
 924 which is here compared to an extended dataset, also including the new data reported here (Figure
 925 2B).

926 **Figure 1.** Schematic illustration of Zn uptake into marine diatoms. Free Zn hexa-aquo complexes
 927 in the artificial seawater medium equilibrate with the transition metal buffer, here the organic
 928 chelator ethylenediaminetetraacetic acid (EDTA). The Zn fraction that is neither organically nor

929 inorganically complexed is considered available for uptake across the cell wall by active
930 transporters (Anderson et al., 1978). The rate limiting step in the uptake kinetics is considered to
931 be the dehydration of the hexa-aquo Zn to form an inner-sphere surface complex at the transporter
932 site (Hudson and Morel, 1990).

933 **Figure 2.** Specific growth rate (A) and surface area normalized Fe uptake rates (B) as a function
934 of the bioavailable Fe concentration (Fe') in the culturing medium. A). The open ocean species
935 studied here are able to maintain higher growth rates at low Fe' than the coastal diatoms
936 previously studied by Sunda and Huntsman (1997). B). The observed Fe uptake rates under
937 similar Fe'-limiting conditions were found to be in good agreement with this previous work.
938 Confidence (dark green) and prediction (light green) intervals of the previously published
939 relationship are given at significance levels of 95 %.

940 **Figure 3.** Distribution of Zn and its isotopes during uptake into cultured marine diatoms. A).
941 Zn/C ratios in this study compared to literature data (grey symbols and green curves). In the
942 present study, bioavailable Zn has been kept constant (vertical dashed blue line) at variable
943 degrees of Fe-limitation. The variability in C-normalized Zn quotas found here is larger than
944 previously reported (blue whisker) by Sunda and Huntsman (1992), and this variability is later
945 shown to be related to medium Fe'. The 25th and 75th percentiles of the dataset are marked by the
946 bottom and top edges of the blue whisker box, and the most extreme data points are given as
947 extended black lines and paler blue shading. B). Surface area normalized Zn uptake rate as a
948 function of the specific growth rate. The growth rate of *Chaetoceros sp.* is strongly suppressed
949 at low medium Fe' (see later) and also generally showed surface area normalized Zn uptake rates
950 that were about half of those for *T. oceanica*. C). Zn isotope fractionation ($\Delta^{66}\text{Zn}_{\text{biomass} - \text{medium}} =$
951 $\delta^{66}\text{Zn}_{\text{biomass}} - \delta^{66}\text{Zn}_{\text{medium}}$) as a function of surface area normalized Zn uptake rates. The generally
952 high Zn uptake rates found for *T. oceanica* consistently come with a 0.2 ‰ preference for light
953 isotopes associated with the biomass. The *Chaetoceros sp.* biomass was characterized by much
954 more variable signatures, with the most negative values at high Zn uptake rates and an increasing
955 preference for heavy Zn isotopes at lower uptake rates.

956 **Figure 4.** Interdependence of Zn and Fe uptake rates of two different cultured marine diatoms in
957 the set of Fe'-limitation experiments undertaken in this study, all at constant bioavailable Zn.

958 **Figure 5.** The physiological interplay between Zn and Fe' in two different cultured marine
959 diatoms. A). P-normalized intracellular Zn quota as a function of Fe'. A few diatoms cultured at
960 Fe' levels higher than 0.7 nmol l⁻¹, a threshold above which Fe-hydroxides have previously been
961 described to occur in culturing solutions (Sunda and Huntsman, 1995b, 1997), show increased
962 Zn/P ratios. B). Zn and Fe uptake rates as a function of Fe'. The colored lines and band represent
963 fits to the data using the Michaelis-Menten equation (*c.f.*, Section 4.2). Confidence (darker color)
964 and prediction (brighter color) intervals of the given relationship are given at significance levels
965 of 95 %, with the exception of the Fe prediction band, given at 75 %. Fe-limitation has been
966 applied as an external forcing to reduce diatom growth, causing the steep decline in Fe uptake
967 rates at low Fe'. C). The distribution of Zn isotopes with respect to the culturing medium, as a
968 function of medium Fe'. The impact of Zn adsorption to Fe-hydroxides is illustrated by six
969 culturing replicates conducted above the threshold of 0.7 nmol l⁻¹ Fe'. Positive Zn isotope
970 signatures associated with *Chaetoceros sp.* are unlikely to be caused by adsorption to Fe-
971 hydroxides in these Fe'-limitation experiments, as increasingly heavy signatures were
972 consistently recorded away from the threshold for precipitation.

973 **Figure 6.** Cellular Zn quotas over a range of different Fe'-limiting conditions. A). The
974 relationship between the specific growth rate and Fe' for two different cultured marine diatoms,
975 described by the Monod equation (Monod, 1949). B). Data for Zn uptake rates as a function of
976 Fe' are fitted using pseudo-Michaelis-Menten kinetics, which differs from the original equation
977 in that the Zn uptake rate is described as function of Fe' rather than of bioavailable Zn (Michaelis
978 and Menten, 1913). This approach is unusual, but justification for doing so comes from the tight
979 coupling of Zn and Fe uptake rates as presented in Figure 4. C). Intracellular Zn quotas predicted
980 by the Droop equation from specific growth rates and Zn uptake rates. The numbers beside the
981 curves show the changes in calculated Zn quotas as Fe' decreases from optimal to severely Fe-
982 limiting levels.

Figure 7. Schematic illustration of proposed Zn isotope effects associated with uptake into cultured marine diatoms. A). Overview of the described effects as a function of the Zn uptake rate. B). If the dehydration of the hexa-aquo Zn to form an inner-sphere surface complex at the transporter site is the rate limiting step in the uptake kinetics (Hudson, 1998; Hudson and Morel, 1990; Sunda and Huntsman, 1998), light isotopes are expected to undergo this transformation slightly faster than heavy Zn (Bigeleisen and Wolfsberg, 1958; Schauble, 2004; and references therein). The maximum preference for light isotopes is achieved as soon as the cellular Zn uptake rate exceeds the water loss rate at the transporter site. An increasing number of enzymes, per unit area of cell wall, facilitates higher Zn uptake rates, whereas the dehydration at every single transporter site is running at its maximum value with constant Zn isotope fractionation. C). If the cellular Zn uptake rate is down-regulated to values lower than the dehydration rate of the Zn hexa-aquo complex, the preference for light isotopes at the transporter becomes progressively less important, and the biomass signature become isotopically heavier. In other words, conditions close to those of an equilibrium situation between the free and surface bound Zn are established at low Zn uptake rates, significantly lower than the water loss rate. Preferential uptake of heavy Zn isotopes, under conditions that develop towards equilibrium at the transporter site with decreasing Zn uptake rates, are consistent with many organic ligands that might form the active site of this enzyme (Ban et al., 2002; Fujii et al., 2014; Jouvin et al., 2009). D). In the experimental setup documented here, suppressed Zn uptake rates were promoted by reducing the availability Fe to the phytoplankton cell.

Figure A.1. Cellular relationship between Zn/C ratios and bioavailable Zn^{2+} . A). Literature data for various phytoplankton species (Sunda and Huntsman, 1992). B). Schematic illustration on how this dataset can be interpreted as evidence for two distinct uptake mechanisms of high- and low-affinity. A second, additional, uptake mechanism (low-affinity) is turned on as soon as the high-affinity pathway reaches its maximum level of saturation.

Figure A.2. Cellular relationship between Zn/C ratios and bioavailable Zn^{2+} in a linear (left column) and logarithmic (right column) representation. Literature data for various phytoplankton

1010 species (Sunda and Huntsman, 1992) are re-evaluated using an incremental curve-fitting
1011 approach. In this approach curve fits have been obtained with incrementally fewer data included
1012 in the evaluation scheme. The root mean squared error of the Michaelis-Menten equation has
1013 been used as an evaluation criterion to assess the goodness of fit. The literature dataset from its
1014 minimum value up to a Zn^{2+} concentration of 1 nmol l^{-1} has been included in the first curve fit
1015 (A and B). Starting from the same minimum value concentrations up to a Zn^{2+} concentrations of
1016 0.3 nmol l^{-1} (C and D) and up to 0.1 nmol l^{-1} (E and F) were included in the latter two calculations.
1017 Confidence (dark green) and prediction (light green) intervals of the relationships are given at
1018 significance levels of 95%, in addition to the solution of the Michaelis-Menten equation (red
1019 line). The whisker (blue) is identical to that given in Figure 3A and shows the Zn^{2+} concentration
1020 used in this study.
