Editorial

The Design Research Studio on Robotic Fabricated High Rises was conducted for the second consecutive year at the Future Cities Laboratory (FCL) in Singapore. The focus continued on high-rise mixed-use residential typologies, since they dominate large parts of the urban landscape in South-East Asia. Although an unbroken demand for housing space coupled with decreasing availability of usable land resources continues to push the limits of vertical growth, the construction technologies are still rooted in a quite anachronistic industrial paradigm: efficiency and economic factors are the driving factors. The studio challenged established paradigms and investigated how contemporary computer-aided architectural design in combination with robotic fabrication could contribute to more differentiation in the context of large buildings.

The studio projects continued to investigate the potential impact of these technologies by creating robotically constructed 1:50 models of high-rises. Processes and components generated in the previous year served as the conceptual foundation for students in the second year. They were provided with a combination of a vacuum gripper and an elaborated feeder system, which allows them to pick building elements from laser-cut sheet material. Predefined programmes and a robotic control setup in Grasshopper directly linked geometric representation of the computer screen with a robotic building process. This initial setup enabled each group to work from the beginning on with an unlimited number of different parts, unlike to the year before when students had to start building tower models with geometrically very limited and similar elements. Hence the focus shifted away from overcoming technical challenges in the robotic fabrication process to a discussion of the implications of robotic fabrication on architectural design in general and the typology of a high-rise in particular.

The semester started off with a survey of high-rise typologies. Students were challenged to identify typological elements that can be translated into parametric design models and produce differentiation. After the initial analytical phase students developed computational design engines connected to the given robotic fabrication process and started to build iterations of towers. The built models were analysed and discussed leading up to the next iteration of model building, thus forming a constant feedback loop between computational design and robotic fabrication. In that working mode the Design Research Studio produced fourteen 1:50 models of up to 4.0 metres height.

In 2013 the studio was open to master's students from both ETH Zürich and National University of Singapore (NUS). A team of PhD researchers addressed robotic construction in a 1:1 scale, focussing on computational design, constructive systems and fabrication processes. Working in an interdisciplinary robotic test laboratory, the studio and PhD researchers greatly benefited from each other through constant knowledge and technology transfer.

Raffael Petrovic and Michael Budig

Foreword

The work presented in this special issue of the FCL Magazine focuses on work emerging from the design research studios conducted in Singapore by the architecture and digital fabrication team, lead by Profs Fabio Gramazio and Matthias Kohler. The design research studio is a hybrid research format that deals as much with the identifying, shaping and setting of research problems, as much as it does solving them. It is a form of research that shuttles between empirical investigation and creative proposition-making. The design research studio is also and effective and meaningful way of integrating masters students, PhD candidates and postdoctoral researchers into a collective inquiry.

The digital fabrication team have innovated around the design research studio format in the context of Singapore’s famous high-rise and high-density built fabric. The format has enabled them to develop collaborative research and teaching platforms with colleagues and students from the National University of Singapore, and ETH Zürich. The distinctive features of the design research studio – interacting with more conventional modes of scientific inquiry – allows researchers to test, refine and develop compelling visions, and credible technologies and processes that sustainable future cities will require.

The studio in 2013 was conducted with administrative support of the National University of Singapore. The Dean of the School of Design and Environment Prof Heng Chye Kiang, Head of Architecture Department Prof Wong Yunn Chii, FCL director Prof Gerhard Schmitt, and FCL Managing Director Dr Remo Burkhard were involved and highly supportive to integrate the studio agenda in the NUS curriculum in order to allow NUS students to participate.
Robotic and automated productions have taken over large parts of many industrial sectors. Although highly ambitious and sophisticated, most attempts at using robotic processes in architecture remain exceptions, prototypes or even failures at a larger scale, because the general approach is either to automate existing manual processes or to automate the complete construction process. However, the potential of robotic fabrication is not fully exploited if used for the execution of purely repetitive mass fabrication processes. Robots can be controlled individually and thus offer the potential for variety and differentiated assembly – even at large scale. The challenges of diverse construction systems and changing demands for each project need to be taken into account, without limiting the range of design. Existing methods and processes have yet to be negotiated in this context. It is time to think about customised robotic processes, products and planning methods for architecture at large scale. At the SEC Future Cities Laboratory, our Chair of Architecture and Digital Fabrication has built up a laboratory to research the potential of robotic processes in architecture and to develop concrete scenarios for their large-scale application to the design and construction of novel high-rise typologies.
Robotic High Rises
Integrating robotic fabrication in a design research studio

The methodology in the design research studio aimed for the reconsideration of the traditional architectural model by directly linking the digital design process with physical manufacturing and tools. As such, it established a strong correlation between computational design, material systems and robotic fabrication strategies. Since high-rises are strongly rooted in the industrialisation of building, with repetitive elements stacked along the vertical axis, they represent an interesting architectural typology to be challenged by this new design and fabrication paradigm. Some of the main strategies of both studio years are revisited and compared on the following pages.
Physical tools and end-effectors

For the development of a robotic fabrication process in the design research studio the robotic end-effectors become the most crucial physical components. Available mechanical grippers are mostly not flexible enough to grasp pieces of various sizes and geometries, and can hardly be adapted to different assembly concepts. To overcome these limitations a modular gripper system was developed to enable multiple options of mechanical and vacuum suction gripping. Students can design and produce these grippers easily and develop their own specific configurations for the model building process (Fig. 03). While the initial focus was put on the gripper geometries for controlled picking and placing routines, more elaborated concepts were eventually designed with higher functional integration, such as, for example, sensor equipment and high-resolution control valves for optimised vacuum suction grippers.

Since the previously developed grippers with suction cups restricted the building components’ geometries, a second generation of vacuum grippers emerged from the idea to perforate a gripping surface with hundreds of small apertures. These grippers are built out of three layers of thin Plexiglas. The first layer is the perforated surface, with the air-feeding layer below and the third layer covering the feeding cavity from the backside. With this configuration grippers could easily be produced by a laser cutter and customised to the elements’ intricate geometries. Due to the thin build-up of the grippers of only 5 mm, they were particularly well suited for dense assemblies at 1:50 model scale (Fig. 04).

Robotic system

Students and researchers share three customised robotic units. Each one consists of a lightweight Universal Robots UR5 robot arm with six degrees of freedom that is mounted to an automatically driven Guedel axis configuration (Fig. 02). This robotic system enlarges the working space of the robot arm from a range of 85 cm to a construction envelope of 4 m height, 1.7 m width and 2.7 m depth; due to its small operating diameter the robot arm can still reach very intricate locations. This allows for the digitally controlled assembly of complex physical models at the scale of 1:50. In addition, a high degree of modularity accommodates quick modifications of the robotic system, e.g. their height and thus the operating space can be adjusted without the need of additional special tools. Four adjustable base points enable the robotic tower to be levelled and transfer its 1.2 tons to the floor. Overall, this unique robotic setup offers flexible and extensible configurations, thus allowing for a rapid transition of digital designs from computation-only models to real-world robotic construction.
As the lightweight robotic arms employed in the design research studio are equipped with built-in safety systems, they do not need to be sheltered in a safety environment like their industrial counterparts. This feature opens the possibility for immediate human-robot interaction, which, in turn, allows a direct, intuitive and continuous process of refinement and adaptation of the end-effectors by the students. As such, the operating paradigm of the robotic towers is to combine the highest possible level of accessibility, human intervention and safety in the laboratory environment.

Software Tools

In a similar vein to the customisable hardware components, a custom robot programming library called YOUR and a corresponding toolkit of Grasshopper components that are open to end-user modification were developed. These software tools aim at making robot control accessible to students without prior specific knowledge or programming skills. Either students use the toolkit from the Grasshopper visual programming environment or they start from the script editor in the McNeel Rhinoceros 3D Modeler; the former is geared towards those without any programming experience while the latter suits experienced programmers. In either case, students are able to control the robot directly from their computational design environment. By directly assembling components from the Grasshopper toolkit, students are able to set up and control their custom robotic fabrication sequences. This visual programming approach facilitates students in quickly prototyping processes, as they only need to learn how a few essential components work and can then connect them in different ways. Since the text based code defining these components is accessible, students become able to modify them once they acquire more experience in programming and knowledge in robotics. This allows them to introduce more complex assembly logics and more intricate robot motion patterns for material manipulation.

Fabrication techniques

The first aim of the design research studio was to build models as high as possible to gauge the limits of the robotic facilities. Initial towers were stacked configurations and fabricated with simple pick and place fabrication processes, for which the students developed different vacuum gripper systems to glue and place cardboard elements. The design of these grippers had to consider essential fabrication parameters, such as material thicknesses, drying times, and height deviations caused by the applied layers of glue. In the beginning the negotiation between the absolute precision of a computer model and the approximation of the material reality mediated by the robot had been the major challenge. Later phases led to the emergence of fabrication strategies, which utilised the robots inherent manufacturing potential as unique drivers for the architectural design.

Picking and placing

One early concept deployed in the design research studio investigates how models can be built through the robotic aggregation of a very large number of small identical components resembling a “constructive 3D printing” process. In order to achieve this goal in an efficient manner, a custom end-effector incorporating a feeder system as well as an automated gluing device have been developed. Using spray glue, this system can hold several hundred pieces at a time and consequently speeds up the construction process by minimising the distance the robotic arm has to travel for placing each individual piece. One of the towers produced with this process consists of more than 15,000 cardboard pieces of two different geometries. Here the challenge is to realise structural systems that are able to cantilever outwards from a vertical core system (Fig. 05).
Another fabrication concept focuses on the seamless integration of the laser cutter, allowing students to produce and assemble elements with different sizes and geometries within an efficient workflow. Since the picking point varies for each piece, a corresponding feeder system and visual programming setup are developed. The cardboard containing the prefabricated elements gets constrained to fit into the robot’s workspace. The individual sheets are then placed directly on the feeder that contains a gluing station. Algorithms are used to generate the layout of the elements on the laser-cut cardboard sheets, and to coordinate the picking, gluing and placing movements of the robot (Fig. 06).

Material deformation processes

Beyond picking and placing strategies the integration of material deformation processes further explores the potential of the robot in its unique capacity to produce bespoke parts departing from identical, mass-produced elements. In a first step, the implementation of a folding process allows to enhance the picking and placing of cardboard pieces by enabling the production of large numbers of geometrically differentiated elements. The next iteration of this process uses thin aluminium sheets, which are bent to more precisely defined angles. The process makes use of two mechanical grippers, one holding the piece in place while the other, mounted directly to the robotic arm, grips the sheet and rotates it around the stationary one – thus controlling the geometry of the folding process (Fig. 07). As a result, by robotically bending each piece in two opposite directions, each sheet becomes a structurally stable wall element. The subsequent picking and placing process of the folded wall elements in layers is controlled by an algorithmic process, which ensures the continuous vertical load transfer by specifically defining the horizontal intersections between the different layers. This proves to be a powerful strategy to exploit the robot’s potential of complex spatial movements to integrally inform the applied material’s geometry as well as its assembly. In contrast to simple picking and placing, the robot plays an active role in the form-giving process of the individual component.

Three additional projects enhance the geometric freedom of the form-giving capacity of the robotic arm by integrating a heat gun into the process. One concept involves bending acrylic stripes at multiple points to create a tower’s primary structural system. After the thermal deformation, the pieces are cooled down with pressurised air in order to avoid retraction and increase assembly speed (Fig. 08). A similar process is used in another project for twisting acrylic sheets and producing a geometrically complex facade louver system. To integrate the previously developed picking and placing process with the material deformation, a combined mechanical and vacuum suction gripper was developed (Fig. 09).
An entirely different approach to robotic material deformation is showcased by a project using generic paper strips as main building material. By connecting two overlaid paper strips at one point and then sliding their relative position before connecting them again, it is possible to produce geometrically highly differentiated building components with undulating geometries (Fig. 10). This process includes the development of a gripper that can pinch two stripes of paper and then staples them together to fixate their final positions. The resulting wall elements are self-stabilising and can be layer-wise assembled into an expressive high-rise structure. As the produced component geometries are a direct result of the material’s intrinsic capacities, the process is parameterised in order to seamlessly connect the digital to the physical model, and to enable adjustments in multiple feedback loops.

Integration in architectural concepts

The second studio year builds upon previously designed fabrication concepts and revaluates these processes in correlation with algorithmic design strategies. The initial setup allows students to start building physical models from the beginning on – thus shifting the focus of the investigation away from digital fabrication experiments towards the development of specific computational design engines, which maximise the potentials of the previously developed robotic fabrication methods and techniques.

Connecting algorithmic design and robotic fabrication

By robotically building physical models and analysing aspects such as structural behaviour, material performance and overall architectural qualities, the students were able to materially inform and specifically adapt their computational design engines in iterative steps, whereby the empirically gained results were further used to rethink and to advance the fabrication process itself (Fig. 11). As an example, some processes demand for the integration of optical sensors that would enhance fabrication precision and allow the implementation of particularly complex manipulation sequences. Sensor technology also enables the integration of human-robot cooperation in a seamless manner as the process could autonomously stop when a manual intervention would become inevitable (Fig. 12). Other projects question the fabrication suitability of a given material system and design a completely new robotic fabrication method that optimises the robot capabilities to become the key driver to their design (Fig. 13).
**Fig. 13** The robot picks extruded Styrofoam cubes and moves them through the hotwire along a computed path, thus utilising the robot’s potential for performing spatially programmed fabrication tasks.

**Outlook**

The design research studio offers a unique experimental test bed, giving the physical architectural model a new meaning and revaluing its importance in the combination with digital design tools. The empirical developments of the designs in correlation with the physical artefact obliges students to deeply and creatively engage with robotic fabrication logics, which become, in turn, a crucial part of the design. The iterations of high-rise models involve continuous feedbacks between physical result and digital design concept. Beyond that, the models reach a complexity (both formal and structural), which could not be manually achieved. The robot thus catalyses new design explorations and avoids conventionally split design and fabrication sequencing, where the final design data gets handed over to a completely separated fabrication process.

Within this scope of directly linking the digital design process with robotic manufacturing as well as with its computational and physical tooling, twenty-seven 1:50 models were produced in total in the studios 2012 and 2013. Here, the consistent interaction with the robotic process leads to a direct and sensual understanding of the tectonic qualities in the model. This exposure to the process of making also requires a profound understanding of the tools and their effects on material and geometric shapes. The role of the architect is challenged here, where design opportunities become sustained in physical space through the adoption and even invention of novel tools and techniques. This design research methodology proves to be a valuable experiment on the way towards a deeper conceptual integration of robotic fabrication paradigms in the design process of novel large-scale architectural typologies.

Sequential Frames
Bedok Area

The project Sequential Frames defines the interior spaces of a high-rise not by enclosure, but by computationally programmed cut-outs in a sequence of densely placed shear walls. Here, a computational design process defines these cut-outs by negotiating between force flows, calculated from top to bottom, and the desired architectural typologies for the mixed-use programme of the tower. The 5,200 wall elements are made from paper stripes that are robotically cut after having been placed into a vacuum clamp at specific angles. The robot then folds the cut piece, applies glue and places the wall onto the model. Despite the assembly of supposedly geometrically simple elements, this approach towards fully integrated computational design and robotic fabrication routines allows highly articulated designs with a large variety of interior spaces.
The resolution of the primary load bearing structure is increased, while the individual wall thickness is decreased. Walls no longer frame a room but only an architectural programme. Interior spaces are not defined by enclosure, but by programmed cut-outs in a sequence of densely placed walls.
Design Iterations
Multiple connected and curved open shapes turned out to be the optimal solution, combining the behaviours of the previous two models (above). Tower 1 consists of 1200 wall elements and measures 1.6 metres in height.
Tower 2 – Computational Design

The second tower was built to investigate strategies for the design of multiple housing configurations in a shear wall system by a sequence of wall cut-outs. The wall system was further parametrised by adding a cut-out shape, defined by a specific cut-out length and a beam height (right page, top). These cut-out walls were populated on curved floor plans, following a simple random distribution pattern. The floor plates vary slightly over the height of the tower, giving the tower a sinuous silhouette.

The design is based on the following wall parameters: a) length, b) height, c) cut-out length, and d) beam height.

Computational degrees of design freedom of tower 2.

Tower 2 The second tower was built to investigate strategies for the design of multiple housing configurations in a shear wall system by a sequence of wall cut-outs. The wall system was further parametrised by adding a cut-out shape, defined by a specific cut-out length and a beam height (right page, top). These cut-out walls were populated on curved floor plans, following a simple random distribution pattern. The floor plates vary slightly over the height of the tower, giving the tower a sinuous silhouette.
The tower consists of 1,440 wall elements and 82 floor elements and measures 3.4 metres in height.
Tower 3 – Computational Design

In the third tower the group optimised their organisational design script. Floors are no longer filled up randomly but with a set of predefined flat types. A flat type consists of a sequence of specifically cut out walls (right page, top). These flat types can have different lengths resulting in different room configurations – from a studio to a four bed apartment (right page, bottom).

Regarding the vertical organisation logic, the continuous force flow around the wall apertures is calculated from top to bottom. Each wall adjusts its opening’s geometry, negotiating between the required structural performance and the desired cut-out for the flats. This makes the appearance of each flat different even if they are of the same type.

Five different versions of flat type distribution in the tower

Each floor plan in the tower is unique. The numbers indicate the flat type of each apartment on the floor. The different flat types are generated by the same computational design engine.
The floorplan shows, how the distance between the shear walls is minimised according to specific functions.
The final model is 2.05 metres high. It consists of 450 wall elements, 66 floor elements and 434 window elements.

The two images of the model show the same flat type, but on two different floors. Adjusting every wall’s geometry to the local force flow makes the appearance of each unit unique.

The relation of the tower and its context, and the development of the vertical structural articulation.
Final Tower  After building three iterations using the initial pick and place process, the team explored more elaborated approaches to robotic fabrication. Here, cutting and folding the paper reduced the fabrication time drastically, enabling the group to substantially increase the number of walls.
The wall geometry is articulated in such a way to be manufactured by the robotic folding process.

The design is based on the wall parameters: first, for length, height, and type, second, on the load-bearing parameters for position, length, and force impact, third, on the opening parameters for length and geometry, and finally, on additional values for facade (length and direction of fold) and the robotic fabrication process (folding and cutting angles, placing position).

Branching and merging Logic: the computational design engine was extended to solve the meeting points of several shear wall slabs. Walls closer to each other than a certain distance merge into one.

Mock-up of the final model in 1:50 scale.

The wall geometry is articulated in such a way to be manufactured by the robotic folding process.
Robotic paper folding - the robotic setup consists of a mechanical gripper able pick thin paper stripes, a gluing station and a custom designed vacuum clamp.

1, 2: The robot picks a paper stripe and places it at a specific angle into the vacuum clamp.

3: The stripe is then cut manually.

4, 5, 6: The robot applies glue and then places the wall onto the model.
Final Tower – Robotic Fabrication
The project is situated in Bedok, East Singapore. The site is along the ECP highway, connecting Changi airport with the city centre. The highway is separating East Coast Park and an adjacent forest. The group proposes a sinuous overall shape constructed above the highway, reconnecting the two parks.
The resolution of the primary load-bearing structure is increased, while the individual wall thickness is decreased. Walls no longer frame a room but an architectural programme. Interior spaces are not defined by enclosure, but by programmed cut-outs in a sequence of densely placed walls.
Final Tower – Interiors
Final Tower
Mesh Towers is based on the computational design and robotic assembly of several slender towers, which merge and separate as they grow in height, structurally supporting each other. Each tower strand is constructed out of stacked Styrofoam units that are oriented away from their immediate neighbouring elements. These units are constructed from geometrically differentiated structural elements, taking advantage of the robot’s capability to accurately move a Styrofoam block free in space: the robot picks one element and moves it through a hot wire along a computationally generated path to fabricate a geometrically complex wall element, ready for assembly. In fact, the intricate wall (and unit) designs follow structural guiding curves to achieve continuous load transfers throughout the whole tower. As such, their dimensions are locally adjusted according to their specific position within the tower, and, in addition, provide a large variety of public programmes connected through a network of bridges and trails.
Since the students were initially limited to build models from two standardised cardboard elements, they dissolved the tower strands into a simple floor and wall system.

Volumetric studies to compare a solid block to pencil towers and a mesh tower structure.
Design Iterations

Tower 1

Tower 2

Tower 3

Tower 4

Final Tower

Petrus Aejmejlaeus Lindström, Pun Hon Chiang, Ping Fuan Lee
Tower 2
Duplex stacking – the units of the previous tower were enclosed by four walls. In this tower the group reduced the number of walls per unit to only two walls in order to provide openings. This made it necessary to rotate each unit by 90 degrees to make the towers structurally stable. To keep the strands as thin as possible the group decided to design each apartment as duplex unit in order to create an appropriate overall floor area.

Tower 1
The tower consists of only two different elements, floors and walls, which are assembled in a simple pick and place process.
Tower 3: Rotation - in the previous tower every second unit directly faces a neighbouring unit. To avoid this lack of privacy the group introduced a rotation of the tower strands to orient neighbouring units away from each other.
Tower 4 – Computational Design

Folded wall generation – the angles for the cardboard folding are calculated from the vertical force flow through the towers. The geometry of the folds follows the direction of the loads and transfers it directly to the lower walls.

Circulation system – an external staircase spirals around each tower strand, connecting the public nodes of the overall structure.
Tower 4 consists of 620 individually folded cardboard walls.
Since robotic folding of cardboard elements turned out to be heavily restricted regarding structural performance and geometric freedom, the design and fabrication exploration was expanded towards volumetric materials, which, ultimately, led to the development of a unique robotic foam cutting process.
Wall generation - each wall consists of two components. An algorithm defines a flat centre plane for the fabrication process, since the end-effector is picking the elements from the flat side and creates the curved outlines by moving through the hot wire cutter.

Sample wall geometry - one of two components, which are individually cut by the robot and glued to comprise one complete wall element.

First assembled model - overall, each unit consists of six pieces: Two floor plates and four wall elements.

Final Tower – Computational Design
Robotic cardboard folding - the laser cut cardboard sheet is placed in the clamp, the robot bends it to the desired angle, hot glue is then applied to stabilise the fold and avoid retraction. The piece is rotated 180 degrees and to create a second fold.

Wall production data - the robotic process needs two profile curves and two force lines for each wall to calculate and cut their individual shapes.
Robotic Foam Cutting
The robot picks the piece and moves it through a hot wire along a computationally generated path to fabricate each wall element.

Feeder System and Hot Wire
The hot wire is tensioned with a spring. This makes the wire more flexible and thus durable.

Sequential diagram of the foam-cutting process
Final Tower – Robotic Fabrication
The mesh towers are located in a dense and architecturally historically 'sensitive' area in Tiong Bahru. At the time of the studio in 2013 the project site was estimated as the most expensive in Singapore up to date. The tower typology attempts to have as little footprint as possible in order to maintain the lower density of the adjacent buildings to the East.
Final Tower – Elevation
Wall type generation – the walls articulate specific architectural functions of the apartments, like kitchens or bathrooms.

Duplex unit floor plan – the entrance to the duplex units is located at the bottom floor. The second level, containing the private rooms, is accessible through an inner void. Both floors have exterior spaces.
Final Tower

Cross section of final tower
The project Vertical Avenue proposes a spiralling circulation system with a range of different public programmes distributed vertically throughout the tower. The computationally designed spiralling ramp system connects several structural cores where residential units are arranged in clusters. The integration of sensors allowed for both matching the needed precision in the placement of components as well as the seamless integration of manual processes complementing the robotic manipulation. Additionally, the project makes use of digitally controlled thermal deformation and assembly of facade elements. This design and fabrication concept ensures a robust yet open approach towards robotic assembly, allowing the physical manipulation of a multitude of building elements into a differentiated high-rise structure.
Concept diagram – the concept of the void deck is transformed into a spiraling circulation system by computationally controlling and distributing public spaces along three tower strands.

Shop houses represent the oldest urban typology in Singapore, containing shops, restaurants or cafes on their ground floor with a residential unit on top.

Void decks – the ground floors of Singapore’s public housing blocks are usually left empty for public programmes.
Design Iterations

Tower 1

Tower 2

Tower 3

Final Tower
The first tower was used to test strategies of densification in a high-rise. It consists of four cores. Along these cores a double tube-like residential unit is stacked up. The units become smaller towards the middle of the tower, in order to create an inner void. Every second unit is rotated by 90 degrees to further differentiate the overall structure.

In the second tower the void decks are introduced. Every sixth floor is left empty, articulating clusters of residential units. These clusters act as Vierendeel trusses, leaving the void decks free of structure. The apartments rotate freely around their centre, creating different views and trying to connect to the next void desk cluster.
In the third tower the group realised their idea of the spiral. They inverted their computational design from trying to create a spiral by rotating each unit to first creating the spiral and from that the void deck clusters. The facade is set back in order to provide self-shading. If the facade is set back too deeply it is split to create a balcony.
In the final design, the group added an acrylic sheet bending process to their robotic fabrication setup in order to further differentiate the towers’ facades.
Without a system to transmit the weight of the walls to the core, the walls sag down.

Vertical Avenue

Circulation system - the three cones are the primary circulation system. The elevator stops only at each void deck. Residents use a secondary spiralling staircase to reach their apartments.

Structural system - each of the void deck clusters supports itself, acting as a Vierendeel system. The three thin cones are stabilised by the ramp.

Structural tests - without a system to transmit the weight of the walls to the core, the walls sag down.
The robot bends each acrylic stripe one or two times, depending on the amount of reflection desired in the facade. The piece is placed in a clamp, controlled via the fabrication script. It is then heated to 300˚C for about 20 seconds (1). Once the material is flexible enough the robotic arm bends the piece to the required angle.

Prefabricated facade elements – since the gripper for the bending process is radically different than the one used to place the walls and assemble the tower, all the facade pieces had to be prefabricated. After being bent the element is placed on a numbered print of it’s generated outline to check for accuracy and to sort them in the correct order.
Facade placement process – the robotic arm indicates the position of the prefabricated facade element’s fold. The acrylic piece is then glued manually to increase speed.

Wall placement process – the robot places each storey’s walls in a radial sequence to avoid collision with the model. After finishing one cluster of residential floors it moves upwards, along the tower spiral's trajectory and commences the assembly of the next units.

Production data for the final tower – all data needed for the production of the final model is generated in the Grasshopper computation design environment. The laser cut file for each piece, including the scan pattern for the facade engraving, the bending data for the robot as well as the placement data.
Final Tower – Robotic Fabrication
The group identified the main access corridors around the site and positioned the building in a way to direct the pedestrian streams into their spiralling park. The project continues the surrounding streets to the sky.
The continuous ramp is free from structure and can house any public programme, from hawker centre to playground. The circulation system adapts to the inclination of the connection surface between the individual tower strands. A low inclination is an open ramp, increased steepness requires serpentine.
