Selective Production of Carbon Monoxide via Methane Oxychlorination over Vanadyl Pyrophosphate

Vladimir Paunović, Guido Zichittella, Réne Verel, Amol P. Amrute, and Javier Pérez-Ramírez*

Abstract: A catalytic process is demonstrated for the selective conversion of methane into carbon monoxide via oxychlorination chemistry. Therein, HCl is added to a CH₄-O₂ feed to facilitate the C-H bond activation under mild conditions, leading to the formation of chloromethanes, CH₃Cl and CH₂Cl₂. The latter are oxidized in situ over the same catalyst, yielding CO and recycling HCl. A material exhibiting chlorine evolution via HCl oxidation, high activity to oxidize the chloromethanes into CO, and no ability to oxidize CO is therefore essential to accomplish this target. Following these design criteria, vanadyl pyrophosphate (VPO) was identified as an outstanding catalyst, exhibiting a CO yield up to ~35% at 96% selectivity and a stable behavior. These findings constitute a basis for the development of a process enabling the on-site valorization of the stranded natural-gas reserves using CO as a highly versatile platform molecule.

Methane, the principal constituent of natural gas, is an important energy resource and an attractive feedstock for the manufacture of chemicals and fuels. However, >30% of the abundant natural-gas reserves are allocated in small reservoirs and/or remote areas, wherein the high transportation costs of methane and marked capital expenditure of the existing syngas-based gas-to-liquid (GTL) technologies hamper their efficient exploitation. Consequently, copious amounts of natural gas retrieved from these stranded wells are nowadays burnt to reduce the anthropogenic greenhouse gas emissions - the global warming potential of CH₄ is >21 times higher than that of CO₂. Disparagingly, the so-called flaring wastes around 3.5% of global warming potential of CH₄ is retrieved from these stranded wells are nowadays burnt to reduce the anthropogenic greenhouse gas emissions - the global warming potential of CH₄ is >21 times higher than that of CO₂. Disparagingly, the so-called flaring wastes around 3.5% of global warming potential of CH₄ is, which is for the manufacture of commodities (<10%). This alarming situation calls for the development of modular, decentralized processes for the economical harvesting of the stranded gas.

The catalytic oxyhalogenation of methane, comprising its reaction with a hydrogen halide (HCl or HBr) and oxygen, is an attractive approach to satisfy these objectives as it enables direct methane functionalization under moderate operating conditions (~1 bar, <853 K). This route has traditionally targeted the production of methyl halides (CH₃Cl and CH₃Br), platform molecules equivalent to methanol that can be transformed into a wide spectrum of value-added chemicals and fuels via the halogen elimination step in the form of hydrogen halide. Recent reports demonstrated the high selectivity to halomethanes over LaOCl and CeO₂ in oxychlorination, and over CeO₂ and vanadyl pyrophosphate (VPO) in oxybromination. Moreover, the oxyhalogenation of methane over catalysts with mild oxidizing properties such as LaOCl in oxychlorination, and FePO₄ and VPO in oxybromination led to CO as the dominant oxidation product, with only marginal CO₂ production. These findings hint an extra potential of the route in the form of an effective method to exploit the natural gas feedstock for on-purpose CO production, which is a key building block in the manufacture of numerous commodities. In this way, the highly endergonic steam reforming and coal gasification, commonly practiced today to obtain CO, could be substituted by an exergonic halogen-mediated process. Nevertheless, this application of the oxyhalogenation reaction has not been considered to date, probably due to the fact that CO was never produced at a selectivity exceeding 50%, which would necessitate complex downstream separation train. Alternatively, a two-step process can be sought, involving the selective methane oxyhalogenation over one catalyst, followed by the oxidation/hydrolysis into CO over a second catalyst. Although the latter step was typically studied with an aim to convert the halomethanes into CO₂, catalysts such as alumina and La-based materials could yield CO with a relatively high selectivity, which however depends on the nature of a halomethane. Still, an integration of the halomethane formation with their oxidation/dehydrochlorination into CO over a single catalyst is highly desirable in view of process intensification, but is rather challenging from the point of catalyst design as it requires a fine balance between the catalyst activities in two reactions. In such a hypothetical process, the use of HCl as a halogenating agent would be desirable instead of HBr due to the lower corrosiveness and the much higher availability of the former.

Figure 1. CO is the chief carbonylating agent for the production of a wide variety of commodities such as acids, alcohols, and isocyanates. The integration of the oxychlorination of methane with the selective oxidation of the thus obtained chloromethanes into CO over a single catalytic material is an attractive route to valorize stranded natural gas basins.

Herein, we present the one-step selective conversion of CH₄ into CO via oxychlorination chemistry (Figure 1) as an alternative route to valorize the emerging natural-gas feedstock given the great versatility of CO [28] in situ HCl recycling, as well as the reaction exothermicity, enabling heat integration in the subsequent CO-processing steps. Thereby, it is essential to find a catalyst showing a high activity for the oxychlorination of methane to chloromethanes and strong propensity for the selective oxidation of the latter into CO under oxychlorination conditions (Figure 1).

To approach the above targeted catalytic process, a series of bulk materials comprising RuO₂, CeO₂, LaVO₄, Nb₂O₅, TiO₂, and VPO having different oxidation properties [11] were prepared and characterized by X-ray diffraction and N₂ sorption, respectively (Figure S1, Table S2). Their performance in the oxychlorination of methane is compared by taking the temperature at which ca. 15% CH₄ conversion is achieved, T₁₅, as a relative measure of their overall catalytic activity (Figure 2). Their performance in the oxychlorination of methane is compared by taking the temperature at which ca. 15% CH₄ conversion is achieved, T₁₅, as a relative measure of their overall catalytic activity (Figure 2). In contrast to CeO₂ and RuO₂, where evolution of CO₂ is observed, while product distribution at this relatively low conversion level was used to fingerprint their inherent reaction kinetics (Figure 2, bottom). The results are presented on the basis of an increasing selectivity to CO, which is considered here as the principal descriptor of the catalyst performance.

Based on their activity patterns, the catalysts can be classified into four different categories. The first class is represented by RuO₂, a well-established HCl oxidation catalyst [10a] exhibiting the highest activity for methane conversion as inferred from its lowest value of T₁₅. Nevertheless, the oxychlorination reaction over this material leads to a pronounced CO₂ formation, as can be expected from its strong propensity to oxidize CH₂Cl₂, chloromethanes, and possible CO intermediate into CO₂ [8,12]. On the other hand, CeO₂ predominantly produces chloromethanes, in line with previous studies reporting its outstanding selectivity to these products in the oxyhalogenation reaction [11]. The third class of catalysts comprises mild oxidizers such as LaVO₄ and Nb₂O₅ [11] exhibiting low activity for CH₄ conversion (the highest values of T₁₅) (Figure 2). Although CO is the dominant oxidation product, a significant part of the chloromethanes remains unconverted even at high reaction temperatures, hampering thus the closure of the HCl loop. Finally, TiO₂ and VPO show inherently high selectivity to CO and moderate activity in converting CH₄. The unprecedentedly suppressed CO₂ formation over VPO (<1% in selectivity) coupled to the low residual amounts of chloromethanes, make it a highly attractive catalyst for the selective CO production from methane via oxychlorination chemistry. This unique performance of VPO and TiO₂ is understood via a series of catalytic tests (Figure S2, Figure 3). In contrast to CeO₂ and RuO₂, where evolution of CO₂ is enhanced at high reaction temperatures (Figure S2), in the oxychlorination of methane over TiO₂ and particularly VPO, the production of CO₂ remains low in a very broad temperature range (Figures 3a,b). In case of VPO, 33% yield and 96% selectivity for CO are achieved at 836 K. Only trace amounts of H₂ are detected, while HCl conversion is <1.5% (Table S3), which suggests that the biggest part of HCl is recycled in situ in a single reactor pass. The selectivity to CO and CO₂ generally decreases and that to halomethanes decreases (Figure S2, Figures 3a,b) upon raising the reaction temperature, suggesting the consecutive oxidation of the chloromethanes generated in the first oxychlorination step as the plausible pathway of carbon oxide formation. Nevertheless, the latter products might in principle evolve from the direct oxidation of methane over a catalyst, To elucidate the contribution of these two routes to the CO formation over VPO and TiO₂, the direct oxidation of methane (Figure 3a, open symbols) as well as the impact of feed HCl concentration on reaction performance (Figure S3) were also studied. The negligible CH₄ conversion over both VPO and TiO₂ in the direct oxidation at temperatures which are significantly higher compared to those applied in the oxychlorination reaction and an increase in CH₄ conversion upon increasing the inlet HCl concentration, demonstrates the pivotal role of HCl in activating methane and corroborates the oxidation of halomethanes as the principal source of CO over these two catalysts. To support the above-indicated consecutive pathway, the activities of VPO and TiO₂ in the oxidation of chloromethanes are further assessed as presented in Figures 3c-f. In good agreement with the oxychlorination tests, CO is produced with very high selectivity (>99%) in both CH₂Cl₂ and CH₃Cl₂ oxidation over VPO (Figures 3d,f), while in case of TiO₂, the selectivity to CO observed in the oxidation of CH₃Cl (90%) is lower than that obtained in the oxidation of CH₂Cl₂ (>99%). Besides, the light-off curves for the conversion of chloromethanes over TiO₂ are shifted to lower temperatures than that over VPO, indicating its higher activity in these reactions, which at first glance contrasts the results presented in Figures 2 and 3b. This might be explained by the substantially higher activity of VPO in the HCl oxidation reaction (Figure 3h), indicating the higher propensity of this catalyst to evolve chlorine, and thus the enhanced production of the precursor chloromethanes, leading to a higher CO productivity. Besides, inhibition of the chloromethanes oxidation by HCl poisoning of TiO₂, which has been often reported in the catalytic abatement of chlorocarbons over oxide materials, might also contribute to the difference in performance among the two catalysts [9,13]. To check for the latter effect, HCl was co-fed with CH₂Cl₂ and O₂ in the corresponding oxidation test to simulate the conditions of the oxychlorination reaction (Figures 3e,f). The results demonstrate...

Figure 4. a) Methane conversion and product selectivity versus time-on-stream (tos) in the oxychlorination of methane over VPO. b) \(^{31}\text{P}\) nuclear magnetic resonance spectra by spin-echo mapping of fresh and used VPO recovered after x h on stream. Conditions: \(F_{\text{T}}/W_{\text{cat}} = 100 \text{ cm}^3 \text{ min}^{-1} \text{ g}^{-1}\), \(\text{CH}_4:\text{HCl}:\text{O}_2: \text{Ar} :\text{He} = 6:6:3:4.5:80.5, T = 803\) K, and \(P = 1\) bar.

A significant drop in \(\text{CH}_2\text{Cl}_2\) conversion over TiO\(_2\) in the presence of HCl, thus corroborating the inhibitory role of HCl, contributing to the inferior activity of this material compared to VPO in the oxychlorination of methane.

The differences in performance of VPO and TiO\(_2\) in the oxychlorination reaction, as well as those in the oxidation of halomethanes, are further explained by evaluating their activities in CO oxidation (Figure 3h, open symbols). VPO shows much lower conversion of CO into CO\(_2\) than TiO\(_2\) (Figure 3h), which is likely caused by its inherently low propensity to adsorb CO. Nevertheless, in analogy to the \(\text{CH}_2\text{Cl}_2\) oxidation, CO conversion over TiO\(_2\) is substantially suppressed in the presence of HCl (Figure 3h, closed symbols), which might explain the low CO\(_2\) productivity observed in the oxychlorination of methane.

Based on these results, the CO production from CH\(_4\) over VPO can be rationalized by the mechanism comprising HCl oxidation into Cl\(_2\), followed by the gas-phase methane chlorination, which is analogous to that proposed for the methane oxybromination over this material. This is supported by the ability of VPO to oxidize HCl into Cl\(_2\) (Figure 3g), and its low activity in the direct oxidation of methane (Figure 3a), indicating its minor propensity to cleave C-H bonds. Moreover, the temperature window of the HCl oxidation coincides with that of methane oxychlorination, suggesting that the evolved Cl\(_2\) readily reacts with methane. This is in line with literature reports testifying the vigorous kinetics of methane chlorination already at 673 K, and it is also corroborated by the low Cl\(_2\) concentration detected at the reactor outlet (Table S3). The ability of VPO to oxidize HCl at temperatures that are comparable or even higher than those needed for chloromethanes oxidation is uniquely combined with its inherent propensity to suppress the oxidation of CO into CO\(_2\), eventually resulting in a highly selective production of CO from methane via the oxychlorination reaction. It is interesting to note that the oxybromination reaction over VPO yields CO as the principal oxidation product. Still, the generation of CO is generally overwhelmed by the formation of bromomethanes, even at high reaction temperatures, which might be explained by the significantly faster HBr oxidation compared to bromomethanes oxidation (Figure S4). The exceptional CO production via methane oxychlorination over VPO is shown to be stable by a 100 h on stream test (Figure 4a). X-ray diffraction (XRD) analysis of the fresh and used samples recovered after different time-on-stream (Figure S5) indicated the equilibration of the starting (VO\(_2\)P\(_2\)O\(_7\))\(_2\) structure within the first 1 h of operation, which remains unaltered over the whole evaluated period of time. \(^{31}\text{P}\) nuclear magnetic resonance by spin-echo mapping (Figure 4b) showed a major peak centered at around 2500 ppm, which is characteristic for (VO\(_2\)P\(_2\)O\(_7\))\(_2\) phase. This peak is slightly broader in case of the fresh catalyst sample, but shows no significant changes among the used catalyst, in line with XRD.
of methane. Herein, VPO, exhibiting a high selectivity to different redox properties were evaluated in the oxychlorination exhibit the chlorine evolution activity, essential to support the formation of chloromethanes, and the ability to selectively oxychlorination, demonstrating the complexity and versatility of criteria, stating that the optimal catalyst for this process should be also utilized.

In conclusion, we demonstrated for the first time the highly selective one-step CO production from methane via oxychlorination chemistry. Following the simple catalyst design in a liquid form. Alternatively, the on-site water-gas shift of the CO-H2O mixture could generate hydrogen.[17] In this way, traditional syngas-to-chemicals transformations, such as methanol production or Fischer-Tropsch (FT) hydrocarbon synthesis, can be practiced by circumventing the steam-reforming (>2273 K, <100 bar) processes, which are the most energy- and capital-demanding steps of the commercial syngas generation technologies.[1,18] Moreover, H2 derived from renewable sources, such as photocatalytic water splitting or biomass reforming,[19] might be also utilized.

In our study, we demonstrated for the first time the highly selective one-step CO production from methane via oxychlorination chemistry. Following the simple catalyst design criteria, stating that the optimal catalyst for this process should exhibit the chlorine evolution activity, essential to support the formation of chloromethanes, and the ability to selectively oxidize the latter into CO, various materials families comprising different redox properties were evaluated in the oxychlorination of methane. Herein, VPO, exhibiting a high selectivity to halomethanes in methane oxybromination, emerged as an outstanding catalyst for CO production via methane oxychlorination, demonstrating the complexity and versatility of the oxyhalogenation chemistry. A yield of CO up to ~35% at 96% selectivity was achieved over this catalyst under ambient pressure and temperatures <835 K. Its exceptional performance, which was stable over 100 h on stream, constitutes the basis for the development of a modular, decentralized process for the valorization of the stranded natural gas by exploiting CO as a well-established platform molecule for the manufacture of value-added commodities.

**Experimental Section**

Commercial CeO2 was treated at 1173 K, while TiO2-rutile and Nb2O5 were treated in static air at 873 K, respectively, prior to their use in the catalytic tests. RuO2 was prepared by thermal decomposition of RuCl3 at 823 K in static air. LaVO4 was synthesized by co-precipitation of La(NO3)3·6H2O with NH4VO4 followed by hydrothermal synthesis at 453 K for 24 h. After filtration and washing with water and methanol, the powder was dried in vacuum at 373 K and calcined at 873 K. VPO was prepared by refluxing a slurry containing V2O5, benzyl alcohol, and isobutyl alcohol for 3 h. Then, H3PO4 was added (P/V = 1.2) and the slurry was refluxed for 16 h followed by drying in vacuum at 373 K and thermal treatment at 873 K under flowing nitrogen. A heating rate of 5 K min−1 and holding time of 5 h were applied in all thermal treatments of the catalysts. The catalytic tests were performed at 1 bar in a continuous-flow fixed-bed reactor set-up (Scheme S1) using a catalyst weight Wcat = 1.0 g (particle size = 0.4-0.6 mm) well-mixed with quartz (particle size = 0.2-0.3 mm) and a total gas flow F1 = 100 cm3 STP min−1 at bed temperatures, T, in the range of 423-875 K. The molar composition of the mixtures in methane oxychlorination (CH4:OCl2:Ar:He = 6:3.4:5.8:80.5), methane oxidation (CH4:O2:Ar:He = 6:3.4:5.8:86.5), and the oxidation of CH3Cl/CH3Br (CH3Cl/CH3Br:O2:Ar:He = 1:3.4:5.9:81.5), CH3Cl/CH3Br (CH3Cl:CH3Br:O2:HCl/HBr:Ar:H2:He = 1:3.0:6.4:5.9:5.8:86.5), HCl/HBr (HCl2:Ar:He = 6:3.4:5.8:86.5), and CO (CO:O2:Ar:He = 1:3.0:6:4:5:91.5(86.5)) were set using digital mass flow controllers to feed the gases, while CH3Cl/CH3Br were fed by syringe pump and a home-made evaporation unit. Concentrations of the carbon-containing compounds at the reactor inlet and outlet were analyzed online using a gas chromatograph coupled to a mass spectrometer. The concentration of H2 was determined by an off-line gas chromatograph equipped with a thermal conductivity detector. The O2 concentration was quantified using an off-line iodometric titration of the absorbing KI solution, while the HCl concentration was determined by acid-base titration after its absorption into H2SO4 solution. The errors of carbon and chlorine balances were lower than 5%. The fresh and used catalysts were characterized by means of X-ray diffraction, N2 sorption, X-ray fluorescence, temperature-programmed reduction with H2, 31P nuclear magnetic resonance spin-echo mapping, and X-ray photoelectron spectroscopy. More details on catalyst preparation, characterization, and testing are provided in the Supporting Information.

Methods

Catalyst preparation

Commercial CeO₂ (Sigma-Aldrich, nanopowder, 99.9%) was treated at 1173 K, while TiO₂ (Sigma-Aldrich, rutile nanopowder, 99.5%) and Nb₂O₅ (Sigma-Aldrich, 99.99%) were treated at 873 K for 5 h in static air prior to their use in the catalytic tests. RuO₂ was obtained by calcination in static air of anhydrous RuCl₃ (ABCR, 99.9%) at 823 K for 5 h. LaVO₄ was synthesized by dissolving La(NO₃)₃·6H₂O (10.83 g, Sigma-Aldrich, ≥99.6%) into freshly prepared 1 M HNO₃ (100 cm³, Fisher Chemical, 65%) followed by gradual addition of NH₄VO₄ (Sigma-Aldrich, ≥99.5%) solution (2.92 g in 100 cm³ of 1 M HNO₃). After adjusting the pH to 7 by dropwise addition of 2 M NaOH, the resulting solution was stirred for 4 h at room temperature and then transferred into a Teflon-lined autoclave. The hydrothermal synthesis was performed under autogenic pressure at 453 K for 24 h. The precipitate was separated by filtration, washed with deionized water, dried under vacuum (50 mbar) at 373 K for 6 h, and calcined at 873 K in static air. Vanadyl pyrophosphate (VPO) was prepared by refluxing a suspension of V₂O₅ (15 g, Aldrich, ≥99.6%) in isobutanol (90 cm³, Acros, >99%) and benzyl alcohol (60 cm³, Sigma Aldrich, >99%) for 3 h. After cooling down to room temperature, H₃PO₄ (Sigma Aldrich, ≥85%) was added to set the molar P:V ratio to 1.2 and the mixture was then refluxed for another 16 h. The resulting solid was recovered by filtration, washed with isobutanol and methanol (Fluka, ≥99.9%), dried in vacuum (50 mbar) at 373 K for 16 h, and thermally treated at 873 K under flowing N₂ (Pan Gas, purity 4.5) for 5 h. The thermal treatments of all catalysts were conducted using a heating rate of 5 K min⁻¹.

Catalyst characterization

Powder X-ray diffraction (XRD) was measured using a PANalytical X'Pert PRO-MPD diffractometer by applying Cu-Kα radiation. The data was recorded in the 10-70° 2θ range with an angular step size of 0.017° and a counting time of 0.26 s per step. N₂ sorption at 77 K was performed using a Quantachrome Quadrasorb-SI analyzer. Prior to the measurement, the sample was evacuated to 50 mbar at 573 K for 12 h. The Brunauer-Emmett-Teller (BET) method (Brunauer et al., J. Am. Chem. Soc. 1938, 60, 309-319) was applied to calculate the total surface area, $S_{BET}$, in m² g⁻¹. X-ray photoelectron spectroscopy (XPS) measurements were performed on a Physical Electronics Quantum 2000 X-ray photoelectron spectrometer using monochromatic Al-Kα radiation, generated from an electron beam operated at 15 kV, and equipped with a hemispherical capacitor electron-energy analyzer. The powdered sample were analyzed at the electron take-off angle of 45° and the pass energy of 46.95 eV. A compensation for sample charging was obtained by referencing all the spectra to the C 1s at 284.5 eV. Temperature-programmed reduction with H₂ (H₂-TPR) was conducted in Micromeritics Autochem II 2920 unit equipped with a thermal conductivity detector and coupled to a MKS Cirrus 2 mass spectrometer. The powder sample (0.05 g) was loaded in a U-shaped quartz reactor between two plugs of quartz wool, pretreated in He (20 cm³ STP min⁻¹) at 623 K for 30 minutes, and cooled down to 500 K in He. H₂-TPR was then performed using 5 vol.% H₂ in N₂ (20 cm³ STP min⁻¹) in a temperature range 500-1100 K with a ramp rate of 10 K min⁻¹. The $^{31}$P nuclear magnetic spectra were acquired using the spin-echo mapping (Li et al., Appl. Catal. 1991, 73,
83-95) or Variable Offset Cumulative Spectrum (VOCS) (Massiot et al., *Solid State Nucl. Mag.* 1995, 4, 241-248) method on a Bruker Avance IIIHD spectrometer equipped with a 9.4T Magnet (162.2 MHz $^{31}$P Larmor frequency). Samples were loaded into 3.2mm rotors and measured using a 3.2mm Double Resonance MAS probe in static mode. For each sample, 7 experiments with a variation of the carrier frequency from 0 to 6000 ppm in 1000 ppm steps were combined. For each offset of the carrier frequency the tuning and matching of the probe was checked and adjusted. The individual experiments used a $\pi/2$-t-$\pi$-acquire spin-echo sequence with a 16 step phase cycle. The $\pi/2$ pulse was set to 1.0 µs and the delay $t$ to 20 µs. A total of 512 scans were acquired with a recycle delay of 0.2 s. The possibility of saturation was tested by repeating a number of experiments with a recycle delay of 2.0 s. No difference between experiments with 0.2 s or 2.0 s recycle delay was observed. The full-echo time domain signals were processed and combined to a final skyline type spectrum using custom written Matlab scripts incorporating functions of the MatNMR toolbox (van Beek, *J. Magn. Reson.* 2007, 187, 19-26).

**Catalytic evaluation**

All the catalytic tests were performed at 1 bar in a continuous-flow fixed-bed reactor set-up (Scheme S1). The quartz reactor (10 mm internal diameter) was loaded with the catalyst ($W_{\text{cat}} = 1.0$ g, particle size = 0.4-0.6 mm) well mixed with quartz particles (particle size = 0.2-0.3 mm) in order to ensure a constant bed volume ($V_{\text{bed}} = 1.8$ cm$^3$) and placed in a homemade electrical oven equipped with a K-type thermocouple fixed in a coaxial quartz thermowell whose tip reaches the center of the catalyst bed. The catalyst was heated in a He flow till the desired bed temperature ($T = 423-875$ K) and stabilized for 30 min under these conditions before the introduction of the reaction mixture. Appropriate amounts of gases: CH$_4$ (PanGas, purity 5.0), CO (Messer, 5 mol.% in He with purity 5.0), HCl (Air Liquide, purity 2.8, anhydrous), HBr (Air Liquide, purity 2.8, anhydrous), CH$_3$Cl (PanGas, purity 2.8), CH$_3$Br (PanGas, 5 mol.% in He with purity 5.0), O$_2$ (PanGas, purity 5.0), Ar (PanGas, purity 5.0; internal standard), and He (PanGas, purity 5.0; carrier gas) were fed using digital mass flow controllers (Bronkhorst) to achieve a desired feed composition at a total volumetric flow, $F_T$, of 100 cm$^3$ STP min$^{-1}$ (space velocity, $F_T/W_{\text{cat}} = 100$ cm$^3$ STP min$^{-1}$ g$^{-1}$). CH$_2$Cl$_2$ (Sigma-Aldrich, 99.5%) and CH$_2$Br$_2$ (ABCR, 99%) were vaporized in the carrier gas stream using a syringe pump (Nexus 6000, Chemyx) and a homebuilt vaporizer operated at 343 K, accommodating a quartz T-connector filled with glass beads. Compositions of the feed mixtures used in the catalytic tests performed in this study are summarized in Table S1.

Condensation of the reactants and products in downstream lining was prevented by heating it at 393 K. The effluent stream from the catalytic reactor was neutralized by passing it through an impinging bottle containing aqueous NaOH solution (1 M). Prior to the analysis of the reactor outlet, the reaction was stabilized under given conditions for at least 1 h. The content of carbon-containing compounds (CH$_4$, CH$_3$Cl, CH$_2$Cl$_2$, CO, and CO$_2$) and Ar was determined on-line using a gas chromatograph equipped with a GS-Carbon PLOT column coupled to a mass spectrometer (GC-MS, Agilent GC 6890, Agilent MSD 5973N). To quantify H$_2$, the product mixture was first passed through

[^a] X denotes Cl or Br.
[^b] The values in brackets refer to the concentration of Ar and He used in the tests in which H₂ production was quantified.
[^c] The values in brackets refer to the concentration of HCl and He applied in the tests where HCl was co-fed with the main reactants.

an impinging bottle containing 0.1 M NaOH solution to neutralize HCl, followed by the collection of remaining stream in a gas bag. The concentration of H₂ in the sampled gas was analyzed using gas chromatograph (SRI 8610C) equipped with HayeSep D and Molecular Sieve 13X packed columns, and TCD detector. The Cl₂ was quantified by an iodometric titration (Mettler Toledo G20 Compact Titrator) of triiodide, formed by purging a stream containing a molecular halogen through an aqueous KI solution (0.1 M), with 0.01 M sodium thiosulfate solution (Aldrich, 99.99%). The concentration of HCl was determined by passing the outlet gas stream through an absorption tray comprising 2 impinging bottles filled with H₂SO₄ solution (Merck, 0.05 M) to absorb HCl, while dissolution of Cl₂ is strongly suppressed in acidic media. The amount of absorbed HCl, n(HCl), was quantified by titration with a NaOH standard solution (Merck, c NAFTAH = 0.05 M) using Eq. 1,

\[
n(\text{HCl}) = (\Delta V_1 + \Delta V_2) \cdot c_{\text{NaOH}}, \text{ mol}
\]

where \(\Delta V_1\) and \(\Delta V_2\) represent the difference in volumes of NaOH consumed for the titration of H₂SO₄ solution after and prior to passing the outlet gas stream in the first and the second impinging bottle, respectively. In all experiments, \(\Delta V_2\) was close to 0, suggesting that most of HCl was absorbed in the first bottle.

The conversion of reactant \(i\), \(X(i)\), \((i\) refers to CH₄, CH₃Cl, CH₃Br, CH₂Cl₂, CH₂Br₂, CO, or HCl\) was calculated using Eq. 2,

\[
X(i) = \frac{n(i)_{\text{outlet}} - n(i)_{\text{inlet}}}{n(i)_{\text{inlet}}} \cdot 100, \% \quad \text{Eq. 2}
\]
where $n(i)_{\text{inlet}}$ and $n(i)_{\text{outlet}}$ are the amounts of the compound $i$ at the inlet and outlet of the reactor, respectively, expressed in moles. In case of HCl and HBr oxidation, conversion of hydrogen halide, $X(\text{HX})$, was determined according to Eq. 3,

$$X(\text{HX}) = \frac{2 \cdot n(X_2)_{\text{outlet}}}{n(\text{HX})_{\text{inlet}}} \cdot 100\, \%$$  \hspace{1cm} \text{Eq. 3}

where $n(X_2)_{\text{outlet}}$ and $n(\text{HX})_{\text{inlet}}$ denote the amount of halogen and HX at the reactor outlet and inlet, respectively, expressed in moles. The selectivity to product $j$, $S(j)$, ($j$ refers to CH₃Cl, CH₂Cl₂, CO, or CO₂) was calculated based on Eq. 4,

$$S(j) = \frac{n(j)_{\text{outlet}} \cdot N_c(j)}{\sum n(j)_{\text{outlet}} \cdot N_c(j)} \cdot 100\, \%$$  \hspace{1cm} \text{Eq. 4}

where $N_c(j)$ corresponds to the number of the carbon atoms in compound $j$. The selectivity to H₂, $S(\text{H}_2)$, was determined using Eq. 5,

$$S(\text{H}_2) = \frac{2 \cdot n(\text{H}_2)_{\text{outlet}}}{n(\text{CH}_4)_{\text{inlet}} + n(\text{CH}_4)_{\text{outlet}}} \cdot 100\, \%$$  \hspace{1cm} \text{Eq. 5}

where $n(\text{H}_2)_{\text{outlet}}$ denotes the amount of H₂ at reactor outlet, while $n(\text{CH}_4)_{\text{inlet}}$ and $n(\text{CH}_4)_{\text{outlet}}$ denote the amount of methane at reactor inlet and outlet, respectively. The yield of product $j$, $Y(j)$, was calculated according to Eq. 6,

$$Y(j) = \frac{X(i) \cdot S(j)}{100}, \%$$  \hspace{1cm} \text{Eq. 6}

The error of the carbon balance, $\varepsilon_C$, was determined using Eq. 7,

$$\varepsilon_C = \frac{\sum n(i)_{\text{inlet}} \cdot N_c(i) - \left(n(\text{CH}_4)_{\text{outlet}} + \sum n(j)_{\text{outlet}} \cdot N_c(j)\right)}{\sum n(i)_{\text{inlet}} \cdot N_c(i)} \cdot 100\, \%$$  \hspace{1cm} \text{Eq. 7}

The error of the chlorine balance, $\varepsilon_{\text{Cl}}$, in the oxychlorination experiments was calculated using Eq. 8,

$$\varepsilon_{\text{Cl}} = \frac{n(\text{HCl})_{\text{inlet}} - n(\text{Cl}_2)_{\text{inlet}} + 2 \cdot n(\text{Cl}_2)_{\text{outlet}} + 2 \cdot n(\text{CH}_2\text{Cl}_2)_{\text{outlet}}}{n(\text{HCl})_{\text{inlet}}} \cdot 100\, \%$$  \hspace{1cm} \text{Eq. 8}

The errors of the mass balances were lower than 5%. Each catalytic data point reported was determined as an average of at least two measurements. After the tests, the catalyst bed was quenched to room temperature in He flow. The catalyst was separated by sieving from the quartz particles and collected for ex situ characterization.

Figure S3. CH₄ conversion and product selectivity versus feed HCl:O₂ ratio in the oxychlorination of methane over VPO. Operation at high HCl:O₂ ratios favors the conversion of methane and slightly decreases the selectivity to CO. Conditions: \( F_{\text{L}/W_{\text{cat}}} = 100 \text{ cm}^3 \text{ min}^{-1} \text{ g}^{-1} \), \( \text{CH}_4:\text{HCl}:\text{O}_2:\text{Ar}:\text{He} = 6:1-12:3:4.5:85.5-74.5 \), \( T = 803 \text{ K} \) and \( P = 1 \text{ bar} \).
Figure S4. a) Product selectivity in methane oxychlorination (MOC, solid bars) and oxybromination (MOB, open bars) over VPO at ca. 15% methane conversion. A switch from MOC to MOB leads to a diametric change in product distribution, demonstrating the rich but complex nature of the oxyhalogenation chemistry. b) Conversion of HX, CH₃X, and CH₂X₂ versus temperature over VPO in the corresponding oxidation reactions. In case of X = Cl, the relative order of the light-off curves of HCl, CH₃Cl, and CH₂Cl₂ oxidation indicates that the rate of chloromethane oxidation is comparable (CH₃Cl) or higher (CH₂Cl₂) than the rate of HCl oxidation. The oxidation of HCl evolves molecular chlorine, Cl₂, which can react with methane to yield chloromethanes (especially di- and polychlorinated methanes, i.e., CH₂Cl₂, CHCl₃, CCl₄) via gas-phase chlorination readily proceeding at T ≥673 K (Olah et al., Beyond Oil and Gas: The Methanol Economy, Wiley-VCH, 2009, 233-278). In such a mechanism, the chlorine evolution through the heterogeneous HCl oxidation is likely to be the limiting step for chloromethane formation over VPO. Based on the proposed consecutive mechanism, comprising chloromethanes production followed by their oxidation over the same catalyst, a high selectivity to CO in the oxychlorination of methane might be explained by the fact that the rates of chloromethane oxidation are approximately equal or even higher (particularly in case of di- and polychlorinated methanes) compared to rates of their formation, resulting thus in a fast consumption of these intermediates once they are formed. In case of X = Br, the temperature for HBr oxidation is shifted by ca. 150 K to lower values compared to that where oxidation of CH₃Br and CH₂Br₂ occurs. On the other hand, gas-phase bromination, exhibiting inherently high selectivity to CH₃Br, onsets at >700 K (Paunović et al., Nat. Chem. 2016, 8, 803-809), where most of the HBr is already converted into bromine. Following the same consecutive mechanism, a high selectivity to bromomethanes in the congeneric methane oxybromination might be rationalized by a significantly higher rate of HBr oxidation compared to that of bromomethanes, which preserves a high concentration of these intermediate compounds. Conditions: Methane oxyhalogenation: CH₄:HX:O₂:Ar:He = 6:6:3:4.5:80.5, HX oxidation: HX:Ar:He = 6:3:4.5:86.5, CH₃X oxidation: CH₃X:O₂:Ar:He = 1:3:4.5:91.5, CH₂X₂ oxidation: CH₂X₂:O₂:Ar:He = 1:3:4.5:91.5, Fcat/Wcat = 100 cm³ min⁻¹ g⁻¹, and P = 1 bar.
Figure S5. a) XRD patterns and b) H₂-TPR profiles of VPO prior to (fresh) and after the oxychlorination of methane for different time-on-stream (x h) at 803 K. The diffractogram of the fresh sample indicates that it is mainly composed of two (VO)₂P₂O₇ phases, in line with the P:V ratio of 1 as found by XRF analysis (Table S4). Exposure of the catalyst to the reaction mixture leads to its reconstruction into the originally present dominant (VO)₂P₂O₇ phase within the first hour. The latter phase is preserved during a 103 h on stream. H₂-TPR profiles of fresh and used samples demonstrate V⁴⁺ to be the dominant oxidation state of V, although a small contribution from V⁵⁺ reduction can be observed, in line with XPS data (Table S4, Figure S6). H₂-TPR profiles of used catalysts are essentially identical, while fresh catalyst shows a slightly broader peak in the region of V⁴⁺ reduction, and a bit more pronounced V⁵⁺ reduction peak.

[a] Determined by XRF.
[b] Calculated based on O 1s and V 2p (3/2) core level binding energies (Figure S6), BE, using formula (Coulston et al., J. Catal. 1996, 163, 122-129): V oxidation state = 13.82 – 0.68(Binding Energy(O 1s) – Binding Energy (V 2p (3/2))).
[c] Calculated based on deconvolution of V 2p (3/2) peak as shown in Figure S6.
**Figure S6.** XPS spectra of VPO samples prior to (fresh) and after (x h) the oxychlorination of methane for different time-on-stream (x h) at 803 K. The binding energies of O 1s (ca. 532 eV) and V 2p (3/2) (ca. 517 eV) showed no significant deviations between the samples and are in good agreement with previous studies on VPO catalysts (Abon et al., *J. Catal.* 1995, 156, 28-36). A deconvolution of V 2p (3/2) peak into two peaks centered around 517.0 eV and 518.1 eV, which correspond to V⁴⁺ (literature values: 516.9-517.1 eV) and V⁵⁺ (literature values: 518.0-518.2 eV) states, respectively, showed the fraction of V⁵⁺ to be 28-39 % (Table S4). These differences in V⁵⁺ content fall in range of the error of the method (ca. 10%).
