1. Abstract

Microspheres made of poly(lactic-co-glycolic acid) (PLGA) are fully biocompatible and biodegradable which renders PLGA microspheres a promising tool in the context of drug delivery. However the adsorption of plasma proteins on micro- and nanospheres is a main limitation of drug targeting. Poly(L-lysine)-g-poly(ethylene glycol) (PLL-g-PEG), physisorbed on flat metal oxide surfaces, has previously been shown to drastically suppress protein adsorption. The goal of the present work was to characterize the efficiency of the protein repellent character of PLL-g-PEG on PLGA microspheres and to show the feasibility of introducing functional groups on the PLGA microspheres via functionalized PLL-g-PEG.

To quantify the adsorbed amount of protein a semi-quantitative method, which uses confocal laser scanning microscopy (CLSM), was applied.

The first part of the experiment confirms the feasibility of introducing specific functional groups on PLL-g-PEG coated PLGA microspheres. In the second part of the experiment PLL-g-PEG coated PLGA microspheres show a drastic decrease of adsorbed proteins by two orders of magnitude in comparison to uncoated PLGA microspheres.

Low protein binding functionalizable microspheres provide a fundamental basis for the design of drug delivery and biosensor systems.

2. Introduction

Colloidal carriers such as micro- and nanospheres are regarded as a promising approach for drug targeting to specific organs of the body in order to reduce drug side effects and to permit a sustained release at the target site [1]. Microspheres made of poly(lactic-co-glycolic acid) (PLGA) are fully biocompatible and biodegradable [2-4], a prerequisite in drug delivery. This is the reason why PLGA is the most commonly used and investigated material for the microencapsulation of therapeutics at present. A serious handicap in drug targeting is the rapid uptake of intravenously injected particulate drug carriers by the cells of the reticuloendothelial system (RES), comprising mainly the Kupffer cells of the liver and the macrophages of the spleen and bone marrow [5]. The filtration mechanism of the spleen also plays an important role in the clearance of colloidal particles [6]. Hence the circulation time of PLGA microspheres in a blood stream in vivo is determined by the physicochemical characteristics of the particles especially their size, surface charge and surface affinity [7]. It has long been known that the removal of particles by the spleen increases with increasing particle size [6]. The adsorption of plasma proteins on the other hand is regarded as the key factor in explaining the organ distribution of microspheres. The presence of specific proteins
(opsonins), e.g., \( \gamma \)-immunoglobulin G (IgG), is known to promote the ingestion by cells of the RES by either specific or non-specific interactions with cell membrane receptors [8]. Therefore not only the total bound protein but also the presence of opsonins and their conformation are expected to influence macrophage uptake. It is also reported that there may be a minimum concentration for certain proteins required to cause an effect, and proteins present in minute amounts are unlikely to be of importance [8].

Several approaches to reduce the protein adsorption on colloid carriers were investigated and published. The plasma protein adsorption on microspheres made of ABA triblock copolymers containing poly(ethylene glycol) (PEG) was reduced by 5 to 7 times compared to microspheres made of pure polyesters [9]. The modification of PLGA particles with PEG is another important and well-known approach to reduce protein adsorption. Gref et al. [10] investigated the influence of the molecular weight and surface density of PEG chains on competitive plasma protein adsorption. A maximal reduction in protein adsorption by a factor of 4 to 5 was achieved under optimized conditions. Poloxamer and poloxamine series adsorbed on polystyrene (PS) particles build a PEG-rich hydrophilic steric barrier that causes a decrease of serum proteins by about 5 times at a 0.3% (v/v) serum concentration. However, at a serum concentration of 50% (v/v) an increase of protein adsorption on coated particles in comparison to uncoated particles was found [11]. Further Harper et al. reported a considerable reduction in the uptake of PEG grafted PS particles by the Kupffer cells compared to naked latex particles [12].

In the present work we focused on the polymer system poly(L-lysine)-g-poly(ethylene glycol) (PLL-g-PEG) (Figure 1), which is known from earlier investigations, performed on flat metal oxide surfaces, to drastically reduce protein adsorption [13,14]. PLL-g-PEG consists of a poly(L-lysine) (PLL) backbone, which is highly cationic at a physiological pH [14] and interacts with the negatively charged PLGA microsphere surface by electrostatic forces. The PLL backbone is grafted with PEG chains, which exhibit the protein-resistant performance. PEG has been extensively investigated for use in a wide array of biomedical applications, and immobilization of PEG on surfaces has long been known to decrease protein adsorption. The protein-suppression performance was found to depend on the molecular weight of PEG, the grafting ratio in the PLL-g-PEG copolymer, and the surface coverage of the polymer[10,13]. Graft copolymers of PLL and PEG have been evaluated in the context of drug delivery for toxicity [15], immunogenicity, immunomodulatory potential, pyrogenicity and biodegradation [16-18], all of which suggest that PLL-g-PEG polymer coatings on PLGA microspheres could be a promising approach for drug delivery.

In the present study we focused on characterizing the efficiency of the protein-repellent character of PLL-g-PEG on PLGA microspheres and on showing the feasibility of introducing functional groups on the PLGA microspheres via modified PLL-g-PEG. Microspheres made of PLGA were prepared
by a spray-dry process and characterized in terms of size distribution and ζ-potential. To investigate
the adsorbed amount of proteins a semi-quantitative method using confocal laser scanning
microscopy (CSLM) was applied.

3. Materials and Methods

3.1 Preparation and Characterization of Microspheres
Poly(lactic-co-glycolic acid) (PLGA : type RG 502 H, Boehringer Ingelheim, Germany)
microspheres were prepared by a spray-dry method [19,20] using dichloromethane as the solvent.
The parameters of the spray-dry process were as follows: 45°C air temperature; 600 Nl/h air flow and
3mL/min pump control. The microparticles were washed with water, collected on a 0.45 µm
cellulose acetate membrane filter and subsequently dried under vacuum for 24 hours.
The size and size distribution of the microspheres were determined using low angle laser light
scattering (LALLS) (Malvern Instruments Ltd., UK). Calculation of particle size was based on Mie’s
theory accounting for the optical properties of the polymer [21]. In order to inhibit agglomeration, the
microspheres were dispersed in Tween 20 during the measurements. Zeta potential measurements
were carried out in phosphate buffer at pH 7.4 (ionic strength = 0.01) by using a ZETA-Meter
System 3+ (ZM3+ 331, Zeta-Meter, Inc., USA).

3.1.1 Coating PLGA Microspheres with Polymer Mixtures
A low ionic strength buffer HEPES I (10mM N-2-hydroxypiperazine-N-3-propanesulfonic acid
(HEPES) with an adjusted pH of 7.4) was chosen to enhance the electrostatic interaction between the
positively charged PLL-g-PEG and the negatively charged surface of the PLGA microspheres.
Different mixtures of PLL-g-PEG and PLL-g-PEG/PEGbiotin were prepared in HEPES I with
1mg/mL total polymer concentration. The molecular weight of the PLL backbone and PEG side
chains were 20 kDa and 2 kDa respectively. The molecular weight of the biotinilated PEG side
chains was 3.5 kDa. The grafting ratio of lysine units/PEG side chains was 3.3 and the percentage of
biotinylated PEG chains of PLL-g-PEG/PEGbiotin was 31%. Figure 1 and 2 show the chemical
structures of PLL-g-PEG and PLL-g-PEG/PEGbiotin respectively.
10 different mixtures of PLL-g-PEG and PLL-g-PEG/PEGbiotin were prepared such that in the
mixture the ratio of biotinilated PEG chains versus unfunctionalized PEG chains varied between 0
and 31%. 0.1 mL of the appropriate mixture was added to 0.1 mL PLGA microspheres. Both the
polymer and the microspheres had a concentration of 1 mg/mL in HEPES I. After 10 minutes of
incubation the solution was centrifuged (Minispin, Eppendorf, Switzerland) at 87300 g for 13
minutes. Then the supernatant was carefully removed, and the microspheres were dispersed in 0.1 mL HEPES I by stirring the solution using a pipette and subsequent vortexing. (These centrifugation parameters and this dispersion method were used in all of the experiments and will be referred to as centrifugation and redispersion, respectively, from now on in the text.)

0.1 ml of 0.04 mg/mL fluorescently labeled streptavidin, Oregon Green 488 conjugate (Molecular Probes, USA) solution in HEPES I was added. After 45 minutes of incubation in darkness the solution was centrifuged and redispersed in 0.2 mL HEPES I. For the final concentrations see Table 1 and for the coating process see the schematic in Figure 3.

3.1.2 Protein Adsorption on PLGA Microspheres

Representatives of human proteins: human serum albumin (HSA), fibrinogen (Fb), fibronectin (Fn), γ-immunoglobulin G (IgG) (Sigma-Aldrich, USA) were used to test the protein resistance of the PLL-g-PEG-coated PLGA microspheres. A buffer with close to physiological ionic strength, HEPES II (10 mM HEPES with 150 mM/L NaCl, pH 7.4) was used in these experiments. 0.1 mL of the appropriate protein at a concentration of 0.2 mg/mL in HEPES II was added to 0.1 mL of PLL-g-PEG-coated (see previous section) or uncoated PLGA microspheres (used as a reference) which were predispersed in HEPES II at a concentration of 1 mg/mL. After an incubation time of 45 minutes the solution was centrifuged and the microspheres were redispersed in 0.1 mL HEPES II. 0.08 mg/mL of the corresponding primary antibody in 0.1 mL HEPES II was added. All primary antibodies against the human proteins were polyclonal antibodies raised in rabbit obtained from DAKO (Switzerland). After 45 minutes of incubation the centrifugation and redispersion steps were repeated. Fluorescently labeled secondary antibody (goat anti-rabbit IgG Oregon Green 488 conjugate, Molecular Probe, USA) at a concentration of 0.08 mg/mL in 0.1 mL HEPES II was added to the microsphere dispersion and incubated in darkness for 45 minutes. After centrifugation the microspheres were redispersed in 0.2 mL HEPES II and immediately measured by CLSM. Table 1 gives a summary of the used concentrations, and the coating process is illustrated in Figure 4.

3.1.3 Cross-Test

In order to test the specificity of the antibody technique one cross-test was performed. PLL-g-PEG coated and uncoated microspheres were exposed to one of the proteins mentioned earlier in 3.1.2, then to a non-corresponding primary antibody and finally to the fluorescently labeled secondary antibody. The coating process was performed as explained in detail in section 3.1.2.
3.2 Quantification of Adsorbed Proteins

A semi-quantification of the adsorbed amount of proteins was performed by measuring the fluorescent signal of the secondary antibody labeling on the surface of the microspheres. The labeled microspheres were let to sediment on a coverslip and cross-sectional images were taken from several microspheres at different heights by using a confocal laser scanning microscope (Figure 5a). The fluorescence intensity (measured in arbitrary units) of the microsphere surfaces was determined as follows: The recorded cross-sectional images were projected onto one plane and the total (integrated) fluorescence intensity was divided by the number of images in one stack (20 images) (Figure 5b). To obtain statistically relevant data this procedure was applied to ten arbitrarily chosen microspheres. In our experiments we used a Zeiss 510 confocal microscope equipped with a 63x 1.25NA Plan-Neofluar objective. For excitations of the fluorophore we used the 488 nm line of an Ar laser. In all experiments the laser power was minimized in order to avoid photobleaching. At each measurement we collected 20 cross sectional images in 500 nm intervals defining the mid plane of the stack at the highest cross sectional diameter of the microsphere.

To assess the absolute amount of adsorbed proteins on the microsphere surface a calibration measurement with an independent quantitative technique (e.g., optical waveguide light mode spectroscopy or radio labeling) is needed.

4. Results and Discussion

4.1 Characterization of Microspheres

PLGA microspheres were analyzed by LALLS for their size distribution. The distribution of the diameter of the PLGA microspheres ranges from approximately 0.1 µm to 10 µm. Because of the limited resolution of the light microscope only microspheres with diameters above 1 µm were examined.

PLGA microspheres displayed a strongly negative zeta potential of $-65.9\pm11.2$ mV.

4.2 Functionalized PLGA Microspheres

In this experiment the feasibility of functionalizing PLGA microspheres was investigated. Mixtures of PLL-g-PEG and PLL-g-PEG/PEGbiotin, with ratios of biotinilated PEG side chains versus unfunctionalized PEG side chains varying between 0 and 31%, were used as a model system. The specificity of the coating was tested with streptavidin Oregon-Green conjugate. Sample preparation was carried out as described in section 3.1.1
Figure 6 shows a linear dependence between the amount of bound streptavidin Oregon-Green conjugate and the proportion of biotinilated side chains in the polymer mixture. These findings agree very well with results form earlier work where the adsorbed amount of streptavidin on biotinylated PLL-g-PEG-coated metal oxide surfaces was quantified using an optical waveguide technique [22]. This correlation confirms the feasibility of introducing functional groups to PLL-g-PEG-coated PLGA microspheres while preserving the full biological functionality of the biotin-streptavidin system. The possibility to produce functionalized protein-repellent microsphere surfaces is crucial for drug targeting. Therefore further functionalizing experiments with peptides as functional group will be performed to achieve the specificity required for drug targeting.

The linear dependence of the measured fluorescent intensity, emitted by the streptavidin Oregon-Green conjugate, on the concentration of biotin indicates that it is feasible to use the fluorescence microscopy method to determine the amount of adsorbed proteins on the microspheres.

4.3 Adsorption and Protein-Resistance Study

In this experiment PLL-g-PEG-coated and uncoated PLGA microspheres were exposed to representatives of human serum proteins to test the efficiency of protein repulsion. See section 3.1.2 for a description of the sample preparation and coating process.

PLL-g-PEG coated PLGA microspheres showed a decrease of adsorbed proteins by two orders of magnitude in comparison to uncoated PLGA microspheres (see Table 2). All the observed particles showed a homogenous distribution of proteins to within the limits of resolution of CLSM.

The result of this experiment confirms that the well-known protein repellent character of PLL-g-PEG, investigated on flat metal oxide surfaces in earlier work [13,14] is transferable to PLL-g-PEG coated PLGA microspheres.

The control experiment, in which the non-corresponding primary antibody was added after protein adsorption, showed a decrease in the fluorescence intensity by two order of magnitudes for PLL-g-PEG-coated and uncoated microspheres comparable to the fluorescence intensity of uncoated microspheres which were exposed to the corresponding primary antibody after protein exposure. Hence the non-specific binding of the antibodies is negligible. The high specificity of the corresponding antibody indicates that the epitopes of the adsorbed proteins are still recognizable for the antibodies.
5. Summary and Conclusions

PLL-g-PEG-coated flat model metal oxide surfaces were widely examined in earlier work [13,14] and have been found to display drastically reduced protein adsorption relative to unmodified metal oxide surfaces. As a next step in the direction of future development in the areas of drug targeting and biosensing, we verified in this work the feasibility of generating protein-repellent biodegradable PLGA microspheres by coating them with PLL-g-PEG. A sharp decline of protein adsorption on PLL-g-PEG coated PLGA microspheres was observed for all tested proteins (HSA, Fb, Fn and IgG). Furthermore we could show that it is feasible to introduce functional groups such as biotin to PLL-g-PEG-coated PLGA microspheres. Low protein binding functionalizable microspheres provide a fundamental basis for the design of drug-delivery and biosensor systems.
