1. Abstract

In the periplasm of *Escherichia coli*, Dsb proteins catalyze disulfide bond formation, isomerisation, and reduction. DsbA and DsbB constitute the oxidative pathway that is responsible for the formation of disulfide bonds. DsbD has a central function in the reductive pathway: it transfers electrons from the cytosolic thioredoxin system across the inner membrane to the periplasm. These reducing equivalents are utilized for disulfide bond isomerization (involving DsbC and DsbG) and for reduction of the *c*-type apocytochromes prior to heme ligation (involving CcmG and CcmH). DsbD consists of three domains: two periplasmic domains in the N- and C-terminal region (nDsbD and cDsbD) and a central transmembrane (TM) domain. Each of these domains contains a pair of essential cysteines: C103/C109 in nDsbD, C163/C285 in the TM domain, and C461/C464 in cDsbD. It was postulated that the catalytic mechanism of DsbD is based exclusively on intra- and intermolecular disulfide exchange reactions. According to the existing model, electrons flow successively from thioredoxin to the TM domain of DsbD, then to cDsbD, nDsbD, and finally to the periplasmic substrate proteins. Available structural information on DsbD included the crystal structure of oxidized nDsbD and of the mixed disulfide between nDsbD and DsbC. In addition, a crystal structure of oxidized cDsbD had been reported.

In this thesis, the catalytic mechanism of DsbD was studied using biophysical and biochemical techniques. To study the intrinsic physical properties of the individual periplasmic domains of DsbD, isolated nDsbD and cDsbD were overexpressed and purified to homogeneity. The determined redox potentials of -232 mV and -235 mV, respectively, demonstrate that electron transfer from thioredoxin ($E_0' = -270$ mV) *via* DsbD to DsbC ($E_0' = -140$ mV) is thermodynamically driven. The direction of the electron flow from the periplasmic domains of DsbD to DsbC was confirmed *in vitro* by reversed phase HPLC analysis of acid-quenched reaction products. The overall electron flow from cDsbD_{red} to nDsbD_{ox} and finally to DsbC_{ox} is rapid at 25°C and pH 7.0. Complete reduction of DsbC is achieved within about 500 s when low initial protein concentrations of 0.25 μM are used. Direct reduction of DsbC by cDsbD is extremely slow ($k_{app} = 57$ M⁻¹s⁻¹). As expected, reverse electron transfer from DsbC_{red} to nDsbD_{ox} or cDsbD_{ox} does not occur.

We then measured the kinetics of all functional and non-functional disulfide exchange reactions between different Dsb proteins. The very fast electron transfer from nDsbD_{red} to DsbC_{ox} or DsbG_{ox} ($k_{app} = 4 \times 10^6$ M⁻¹s⁻¹ and $k_{app} = 2 \times 10^6$ M⁻¹s⁻¹, respectively) ensures effective reduction of these proteins by DsbD *in vivo*. In contrast, one of the fastest nonfunctional reactions, reduction of DsbA by nDsbD, is >1000-fold slower ($k_{app} = 900$ M⁻¹s⁻¹).

¹). Based on the kinetic data, we can conclude that large kinetic barriers separate the oxidative DsbA/B and the reductive DsbC/D systems and guarantee their independence.

We next showed that C109 and C461 form an inter-domain disulfide bond between nDsbD and cDsbD. This finding allowed crystallization and structure determination of the kinetically stabilized mixed disulfide complex between the C103S variant of nDsbD and the C464S variant of cDsbD (nDsbD-SS-cDsbD) that represents an essential intermediate in the catalytic cycle of DsbD. Comparison of the crystal structure of nDsbD-SS-cDsbD with the known structure of the complex between nDsbD and DsbC revealed a strong overlap between the surface areas of nDsbD that interact with DsbC and cDsbD. Consequently, electron transfer from cDsbD to DsbC via nDsbD must involve large relative domain movements. We also solved crystal structures of oxidized and reduced cDsbD and compared them with the cDsbD structure in the nDsbD-SS-cDsbD complex. cDsbD appears to be a very rigid protein that does not undergo significant conformational changes upon disulfide exchange.

Finally, we proved that DsbD rapidly and directly transfers electrons to the reductase CcmG, and showed that another Ccm protein, CcmH, is not required for this process. For kinetic and structural studies, we produced CcmG as a soluble protein that lacks the N-terminal transmembrane helix. Using stopped-flow fluorescence measurements, we showed fast electron transfer from nDsbD to soluble CcmG *in vitro* ($k_{app} = 4 \times 10^5 \text{ M}^{-1}\text{s}^{-1}$). We also synthesized the mixed disulfide complex between the C103S variant of nDsbD and the C83S variant of soluble CcmG (nDsbD-SS-CcmG) and determined its crystal structure. Comparison of the X-ray structures of all three mixed disulfide complexes of nDsbD (nDsbD-SS-DsbC, nDsbD-SS-cDsbD, and nDsbD-SS-CcmG) revealed the structural basis for the intriguing ability of nDsbD to interact specifically and very rapidly with different target proteins such as the membrane-anchored monomer CcmG and the periplasmic dimers DsbC and DsbG.

2. Introduction

2.1 Oxidative protein folding in bacteria

Oxidative protein folding is a composite process by which a reduced, unfolded protein acquires both its native disulfide bonds and native structure (Narayan *et al.*, 2000). Failure to form proper disulfide bonds, or their slow formation in the cell, is likely to lead to protein aggregation and degradation by proteases. In gram-negative bacteria, disulfide bonds are formed in the oxidizing environment of the periplasm. It has been estimated that more than half of the periplasmic and membrane proteins contain at least one disulfide bond (Haebel *et al.*, 2002; Hiniker and Bardwell, 2004; Kim *et al.*, 2003). *In vitro*, disulfide bonds can be formed spontaneously by molecular oxygen, but the rate of this spontaneous formation is much slower than the rate of disulfide bond formation *in vivo* (Anfinsen, 1973; Saxena and Wetlaufer, 1970). Moreover, the number of possible disulfide cross-links increases by around one order of magnitude with each additional cysteine pair. This means that a protein with four pairs of cysteine residues has less than a 1% chance of attaining the correct four disulfides by random oxidation. Indeed, oxidative protein folding *in vivo* is catalyzed by a variety of thiol-disulfide oxidoreductases and requires two enzymatic activities: disulfide bond formation and isomerization of non-native disulfide bonds.

2.2 The superfamily of thioredoxin-like proteins

Thiol-disulfide oxidoreductases that catalyze disulfide bond formation and isomerization in *Escherichia coli* belong to the thioredoxin superfamily. These proteins share two common features: they contain an active site with a C-X-X-C motif (where X is any amino acid) and an overall structure known as the thioredoxin fold. The thioredoxin fold was named after thioredoxin, in which it was first observed (Martin, 1995). However, the thioredoxin fold is somewhat smaller than thioredoxin itself and consists of a central four-stranded β -sheet with three flanking α -helices (Fig. 1). The thioredoxin fold comprises about 80 core residues, but each of the proteins containing it possesses extra residues in addition to the core. Certain sites in the thioredoxin fold can tolerate insertions without disruption of the overall structure (indicated with asterisks in Fig. 1). Thioredoxin is a monomeric 108-residue single-domain protein that, in addition to the thioredoxin fold, has a β -strand and a α -helix at the N-terminus (Fig. 2) (Katti *et al.*, 1990). The periplasmic dithiol oxidase DsbA from *E. coli* is a 189-residue monomer with two distinct domains – a thioredoxin domain and an α -helical domain, which is inserted into the thioredoxin fold between β 2 and α 2 (Martin *et al.*, 1993).

Figure 1. Architecture of the thioredoxin fold. Astrisks indicate sites in the structure at which insertions of residues are found. (Martin, 1995)

Figure 2. Crystal structures of *E.coli* cytoplasmic thioredoxin and the periplasmic thiol-disulfide oxidoreductases: DsbA, DsbC, and DsbG. The thioredoxin fold is depicted in red. Active site cysteine residues are shown in yellow. (Heras *et al.*, 2004; Katti *et al.*, 1990; Martin *et al.*, 1993; McCarthy *et al.*, 2000)

Finally, the periplasmic disulfide isomerase DsbC and its homologue DsbG are homodimers of 216 and 231-residue subunit, respectively, consisting of a N-terminal dimerization domain and a C-terminal thioredoxin domain (Heras *et al.*, 2004; McCarthy *et al.*, 2000). Despite the common C-X-X-C active site motif and the overall structural similarity, the individual members of the thioredoxin superfamily show low sequence identity and vary widely in their oxidizing power and therefore in their function (Martin, 1995).

2.3 Mechanism of thiol-disulfide exchange

Oxidation and reduction of disulfide bonds is mediated by fast thiol-disulfide exchange between the active site cysteines of an enzyme and the cysteines of a substrate protein. The catalytic mechanism of thioredoxin-like thiol-disulfide oxidoreductases involves cycling of their active site cysteine residues between the reduced and disulfide-bonded forms, *via* an intermediate with a mixed disulfide bond between the catalyst and the substrate protein (Fig. 3) (Darby and Creighton, 1995; Frech *et al.*, 1996; Kallis and Holmgren, 1980).

Figure 3. Thiol-disulfide exchange reaction between proteins. (Sevier and Kaiser, 2002)

In the C-X-X-C motif of thioredoxin-like proteins, only the N-terminal cysteine is exposed to solvent, and able to form mixed disulfide with protein substrates. The reaction rates of disulfide exchange between a thiol-disulfide oxidoreductase and a peptide substrate vary between 10^3 - 10^7 $M^{-1}s^{-1}$ (Darby *et al.*, 1998), which is several orders of magnitude faster than disulfide exchange between alkyl thiols (10 - 10^3 $M^{-1}s^{-1}$) (Shaked *et al.*, 1980; Szajewski and Whitesides, 1980). Factors that determine the reaction rates are the pK_a of the N-terminal active site cysteine, the effective concentration and accessibility of the thiol or disulfide groups in the substrate, and the chemical environment of the active site.

2.4 pK_a values, redox properties, and C-X-X-C motifs of thioredoxin-like proteins

Only deprotonated thiols can act as nucleophiles in disulfide exchange reactions. The extent of thiol ionization at any particular pH and, consequently, its intrinsic chemical reactivity are determined by the pK_a of the thiol (Holmgren, 1985; Kortemme and Creighton, 1995; Nelson and Creighton, 1994). Moreover, the pK_a values also determine the intrinsic reactivity of the sulfur atoms even when they are involved in a disulfide bond (Creighton, 1975; Szajewski and Whitesides, 1980). Thus the pK_a values of all sulfurs affect the rates and direction of disulfide exchange reactions. Biophysical studies on DsbA (Grauschopf *et al.*, 1995; Hennecke *et al.*, 1997; Huber-Wunderlich and Glockshuber, 1998; Jacobi *et al.*, 1997; Nelson and Creighton, 1994) and thioredoxin (Chivers *et al.*, 1996; Dyson *et al.*, 1997; Mossner *et al.*, 1998) revealed that the pK_a value of the nucleophilic, N-terminal cysteine thiol of the C-X-X-C motif is a critical factor for the redox properties of thiol-disulfide oxidoreductases. In DsbA, the extremely low pK_a value (~ 3.5 compared to a value of 9.5 for a normal cysteine) of the nucleophilic thiol stabilizes the reduced state of the active site and explains the observation that reduced DsbA is 23 kJ/mol more stable than oxidized DsbA (Grauschopf *et al.*, 1995; Hennecke *et al.*, 1997; Nelson and Creighton, 1994; Wunderlich and Glockshuber, 1993; Zapun *et al.*, 1993). The very low pK_a implicates that the nucleophilic thiol of DsbA is fully ionized and reactive at physiological pH, explaining the high rate of disulfide interchange. These features make DsbA a very strong oxidase. In contrast, thioredoxin is the most reducing member of the family and its nucleophilic thiol possesses a pK_a value of about 7.1 (Mossner *et al.*, 1998). For various DsbA and thioredoxin active site variants and also for the wild type proteins, a correlation between increased redox potentials and decreased pK_a values of the nucleophilic active site thiols was observed (Grauschopf *et al.*, 1995; Huber-Wunderlich and Glockshuber, 1998; Mossner *et al.*, 1998). It has been demonstrated that the dipeptide sequence between the active-site cysteines strongly influences the pK_a values and redox properties of thioredoxin-like thiol-disulfide oxidoreductases (Chivers *et al.*, 1996; Grauschopf *et al.*, 1995; Holst *et al.*, 1997; Huber-Wunderlich and Glockshuber, 1998; Krause *et al.*, 1991; Mossner *et al.*, 1998; Mossner *et al.*, 1999; Rossmann *et al.*, 1997). For example, a proline that follows the nucleophilic cysteine in the active site motif of DsbA (Table 1) seems to be responsible for the oxidizing power of DsbA, whereas a proline residue at the second position of the dipeptide is typical for the reductant thioredoxin (Kortemme and Creighton, 1995; Mossner *et al.*, 1998).

protein	C-X-X-C motif	E_0' , mV	pK_a
thioredoxin	C-G-P-C	- 270 ^a	7.1 ^g
DsbA	C-P-H-C	- 122 ^b	3.5 ^h
DsbC	C-G-Y-C	- 140 ^c	4.1 ⁱ
DsbD	C-V-A-C	- 235 ^d	-
DsbG	C-P-Y-C	- 129 ^e	-
CcmG	C-P-T-C	- 210 ^f	6.7 ^f

Table 1. Active site C-X-X-C motifs, redox potentials, and pK_a values of *E. coli* thioredoxin proteins. (^a – (Krause *et al.*, 1991); ^b – (Wunderlich and Glockshuber, 1993; Zapun *et al.*, 1993); ^c – (Rozhkova *et al.*, 2004; Zapun *et al.*, 1995); ^d – (Collet *et al.*, 2002; Rozhkova *et al.*, 2004); ^e – (Besette *et al.*, 1999; van Straaten *et al.*, 1998); ^f – (Li *et al.*, 2001); ^g – (Mossner *et al.*, 1998); ^h – (Nelson and Creighton, 1994); ⁱ – (Sun and Wang, 2000))

In addition, a histidine residue at the second position of dipeptide appears to stabilize the thiolate anion of DsbA and contribute to its low pK_a (Guddat *et al.*, 1998). Indeed, replacement of the X-X dipeptide in DsbA or thioredoxin by the active site sequence of other thiol-disulfide oxidoreductases shifts the pK_a values towards the corresponding value of related enzyme. The X-X dipeptides are characteristic for the individual members of the thioredoxin superfamily (Table 1).

2.5 Disulfide bond formation and isomerization in *Escherichia coli*

2.5.1 The Dsb protein family

In the periplasm of *E. coli*, formation and isomerisation of disulfide bonds is catalyzed by Dsb proteins that constitute two independent pathways (Fig. 4). The oxidative DsbA/DsbB pathway is responsible for disulfide bond formation (Bardwell *et al.*, 1991; Bardwell *et al.*, 1993; Dailey and Berg, 1993). The oxidizing power utilized by this pathway comes from the membrane-embedded electron transport system. The reductive DsbC/DsbD pathway

Figure 4. Oxidative DsbB and reductive DsbD pathways in *Escherichia coli*. Arrows indicate the direction of electron flow.

guaranties efficient disulfide bond isomerization (Bolhuis *et al.*, 1999; Krupp *et al.*, 2001; Missiakas *et al.*, 1995; Rietsch *et al.*, 1997; Stewart *et al.*, 1999). The reducing equivalents required for maintenance of the catalytically active, reduced state of DsbC originate from the cytosolic thioredoxin system.

2.5.2 The periplasmic dithiol oxidase DsbA

DsbA was the first identified bacterial protein required for disulfide bond formation *in vivo* (Bardwell *et al.*, 1991; Kamitani *et al.*, 1992). It was observed that *dsbA*⁻ strains are hypersensitive to benzylpenicillin, dithiothreitol and metals (Missiakas *et al.*, 1993; Stafford *et al.*, 1999). They show reduced levels of several secreted proteins such as the outer-membrane protein OmpA, alkaline phosphatase, and β -lactamase (Bardwell *et al.*, 1991). They do not exhibit motility because of lack of the properly assembled flagellar motor (Dailey and Berg, 1993). In addition, *dsbA* mutants of many pathogenic bacteria are avirulent since virulence components such as pili and toxins are not properly folded and/or assembled (Peek and Taylor, 1992). DsbA is a strong oxidase that very rapidly and randomly introduces disulfide bonds into a wide variety of substrate proteins. Recently, Hiniker and Bardwell identified 10 cysteine-containing proteins from the *E. coli* periplasm that are *in vivo* substrates

of DsbA. Six of these proteins (PhoA, DppA, Rnase I, FlgI, HisJ, and LivJ) contain at least one known structural disulfide bond (Hiniker and Bardwell, 2004). Upon oxidation of substrate polypeptides, DsbA becomes reduced and is re-oxidized by DsbB (Bardwell *et al.*, 1993; Guilhot *et al.*, 1995; Kishigami *et al.*, 1995; Kishigami and Ito, 1996).

2.5.3 DsbB recycles oxidized DsbA

In 1993, three groups independently identified and characterized the *E. coli dsbB* gene, whose protein product was required for disulfide bond formation in periplasmic proteins (Bardwell *et al.*, 1993; Dailey and Berg, 1993; Missiakas *et al.*, 1993). *dsbB* mutants exhibit the same pleiotropic phenotype as *dsbA* mutants, suggesting that both proteins belong to the same oxidation pathway (Missiakas *et al.*, 1993). This hypothesis was confirmed by the observation that in *dsbB*⁻ strains DsbA accumulates in the reduced state, while in wild type strains DsbA is completely oxidized (Kishigami *et al.*, 1995). The isolation of a DsbA-DsbB mixed-disulfide complex confirmed that DsbA and DsbB interact directly (Guilhot *et al.*, 1995; Kishigami *et al.*, 1995). In addition, Bader and coworkers showed rapid direct re-oxidation of DsbA by DsbB *in vitro* (Bader *et al.*, 1998). DsbB is a 20 kDa inner membrane protein (Fig. 5), predicted to have four transmembrane helices and two periplasmic loops (Jander *et al.*, 1994). DsbB has four essential cysteine residues – one pair in each of the periplasmic loops (Guilhot *et al.*, 1995; Kishigami *et al.*, 1995; Kishigami and Ito, 1996; Kobayashi *et al.*, 1997; Kobayashi and Ito, 1999). The electrons from reduced DsbA first flow to the DsbB C-

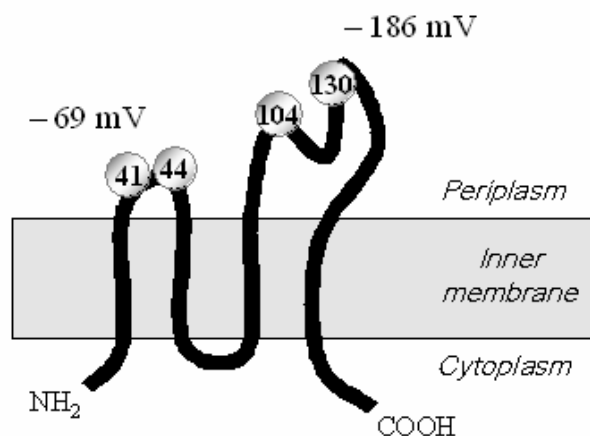

Figure 5. Membrane topology of DsbB. DsbB is predicted to consist of four transmembrane helices and two periplasmic loops each containing a pair of essential cysteines. The redox potentials of cysteine pairs C41-C44 and C104-C130 are -69 mV and -186 mV, respectively (Grauschopf *et al.*, 2003).

terminal cysteine pair (C104-C130), which has a redox potential of -186 mV, and then to the

N-terminal cysteine pair (C41-C44) with a redox potential of -69 mV (Grauschopf *et al.*, 2003). Re-oxidation of the N-terminal cysteine pair occurs through ubiquinone, which, under aerobic conditions, donates the electrons to cytochrome oxidases and finally to oxygen (Bader *et al.*, 1999; Bader *et al.*, 2000). Under anaerobic conditions the electrons are passed from DsbB to menaquinone and then to fumarate or nitrate reductase (Bader *et al.*, 1999). Using purified components, Bader and coworkers showed that quinones could act as direct recipients of electrons from DsbB (Bader *et al.*, 1999). Thus, DsbB has the novel ability to generate a disulfide bond in DsbA by reduction of quinones.

2.5.4 The protein disulfide isomerase DsbC

It has been demonstrated that DsbA can introduce wrong disulfide bonds into substrate proteins and therefore trap the proteins in nonnative conformations both *in vitro* and *in vivo* (Bader *et al.*, 2000; Hiniker and Bardwell, 2004). The incorrectly formed disulfides must be isomerized to the native conformation to allow proper folding of the proteins. The first step in the discovery of the isomerization pathway in prokaryotes was the identification of the periplasmic protein disulfide isomerase DsbC (Missiakas *et al.*, 1994; Shevchik *et al.*, 1994). The *E. coli dsbC* gene was isolated independently by screening for dithiothreitol-sensitive mutations (Missiakas *et al.*, 1994) and as a suppressor of a *dsbA* null phenotype (Shevchik *et al.*, 1994). Like *dsbA*⁻ and *dsbB*⁻ strains, *dsbC* mutants are defective in disulfide bond formation, but the defect in absence of DsbC is much milder (Rietsch *et al.*, 1996). For instance, mutations in DsbC neither affect cell motility nor the formation of OmpA and β -lactamase. The function of DsbC was established using *in vitro* folding assays with model substrate polypeptides and confirmed in expression studies of exogenous proteins in various *dsb*⁻ backgrounds (Darby *et al.*, 1998; Joly and Swartz, 1997; Rietsch *et al.*, 1996; Rietsch *et al.*, 1997; Sone *et al.*, 1997; Zapun *et al.*, 1995). It was found that DsbC is required for the correct folding of proteins with multiple disulfide bonds. Moreover, Joly and Schwartz (1997) demonstrated that overproduction in *E. coli* of heterologous proteins with consecutive disulfide bonds did not require DsbC, whereas the yield of proteins with nonconsecutive bridges was decreased by 50% in *dsbC*⁻ strains (Joly and Swartz, 1997). Recently, Hiniker and Bardwell have shown that two *E. coli* periplasmic proteins, RNase I (4 disulfide bonds) and MepA (6 conserved cysteines), are *in vivo* substrates of DsbA and DsbC (Hiniker and Bardwell, 2004). The quantity of RNase I and MepA was dramatically decreased in *dsbA*⁻ and *dsbC*⁻ strains. In contrast, the levels of two other DsbA-dependent proteins (PhoA and DppA) were unchanged in *dsbC*⁻ strains. PhoA and DppA contain only consecutive disulfide

bonds, whereas RNase I contains one non-consecutive disulfide bond in addition to three consecutive ones. So far the disulfide connectivity of MepA remains unknown. These findings suggest that DsbC is required for the folding of proteins with at least one non-consecutive disulfide bond, whereas DsbA is important for disulfide bond formation in all disulfide-containing proteins translocated to the periplasm. The proposal that disulfide bond connectivity determines whether a protein requires DsbC for its proper folding got further support in the work of Berkmen and colleagues (Berkmen *et al.*, 2005). The authors showed that acid phosphatase phytase (AppA) that has one non-consecutive disulfide bond requires DsbC for its proper folding. However, the activity of an AppA variant lacking the non-consecutive bond is DsbC-independent. Additionally, a homolog of AppA that contains only consecutive bonds and does not need DsbC becomes DsbC-dependent upon engineering of a non-consecutive bond.

DsbC is a V-shaped homodimeric isomerase that belongs to the thioredoxin superfamily. Each DsbC subunit consists of an N-terminal dimerization domain and a C-terminal thioredoxin domain with a C-G-Y-C motif. Sun and Wang (2000) showed that the dimerization of DsbC is required for its function *in vivo* (Sun and Wang, 2000). The crystal structure (Fig.6) revealed that DsbC combines two basic features required for disulfide bond isomerase activity, namely a thiolate active site that can attack and reshuffle substrate

Figure 6. Ribbon diagram of the DsbC homodimer. The N-terminal dimerisation domain and the C-terminal catalytic domain are depicted in pink and green, respectively. Active site cysteine residues are shown in yellow. (McCarthy *et al.*, 2000)

disulfide bonds, and an uncharged surface to bind folding substrate peptides (McCarthy *et al.*, 2000). Both active sites of DsbC are separated by ~ 40 Å and oriented towards the inside of

the “V”. The surface of the cleft between the two arms of the V is lined with hydrophobic and uncharged residues, enabling non-covalent binding of substrate proteins. It was proposed that the cleft can switch between open and closed conformations in order to adjust to the binding partner (Haebel *et al.*, 2002). Substrate binding appears to play a significant role in catalysis by DsbC (Darby *et al.*, 1998). The reactions between DsbC and substrate peptides occur at rates up to 10^5 -fold faster than those involving DsbC and glutathione. Such rate enhancement might be due to considerably increased effective concentrations of the reacting groups upon peptide binding to the catalyst. In fact, mixed-disulfide complexes of DsbC and the peptides are 10^4 -fold more stable than the corresponding mixed-disulfides with glutathione. In addition, the stability of the enzyme-peptide mixed-disulfide relative to the stability of a disulfide bond in a folding protein favours breakage of unstable substrate disulfide bonds and provides the opportunity for the formation of new more stable disulfides. The intramolecular thiol-disulfide exchange reaction between DsbC and a scrambled protein can occur only if the active site cysteines of DsbC are reduced (Joly and Swartz, 1997; Rietsch *et al.*, 1997). *In vivo*, reduction of DsbC is carried out by DsbD (Missiakas *et al.*, 1995; Rietsch *et al.*, 1997). In the absence of DsbD, cytoplasmic thioredoxin or cytoplasmic thioredoxin reductase, DsbC is found completely oxidized *in vivo* (Chung *et al.*, 2000; Katzen and Beckwith, 2000; Missiakas *et al.*, 1995; Rietsch *et al.*, 1997).

2.5.5 The inner membrane electron transporter DsbD

DsbD is a 59 kDa inner membrane protein that consists of three domains: a periplasmic N-terminal domain (nDsbD), a central transmembrane (TM) domain with eight predicted TM helices, and a C-terminal domain (cDsbD) that is again oriented towards the periplasm. The suggested topological structure of DsbD (Fig. 7) was derived from a combination of *in vivo* experiments with alkaline phosphatase fusions and computational algorithms for transmembrane sequences prediction (Chung *et al.*, 2000; Gordon *et al.*, 2000; Stewart *et al.*, 1999). Mutational analyses showed that each of the domains contains one pair of conserved cysteine residues essential for DsbD activity *in vivo* (Chung *et al.*, 2000; Gordon *et al.*, 2000; Stewart *et al.*, 1999). The two invariant cysteines of the TM domain are located within the membrane-spanning region, C163 in TM helix 1 and C285 in TM helix 4 (Fig. 7). DsbD can be split into its three structural domains without loss of *in vivo* activity (Katzen and Beckwith, 2000): simultaneous expression of the three separated DsbD domains restores reduction of DsbC and cytochrome *c* maturation. However, when any of the three domains is removed from the system, oxidized DsbC accumulates and the formation of holocytochromes is

Figure 7. Model of the electron flow from thioredoxin (Trx) to DsbC via DsbD. Electron transport is proposed to occur exclusively through inter- and intramolecular disulfide exchange. Arrows indicate the direction of electron flow. Essential cysteines are depicted as circles with corresponding numbers.

abolished. These results indicate that all three domains are required for DsbD activity, but do not need to be part of a single polypeptide. Additionally, it has been shown that both nDsbD and cDsbD are oxidized when the TM domain is not present, whereas absence of nDsbD does not affect the redox state of the other two domains. cDsbD is required for the reduction of nDsbD, but not the TM domain. Taken together these results demonstrate that electrons within the DsbD molecule flow from the TM domain to cDsbD and finally to nDsbD. The detection of apparent reaction intermediates in the form of mixed disulfides indicated direct electron flow from thioredoxin via DsbD to DsbC or CcmG (Katzen and Beckwith, 2000; Krupp *et al.*, 2001). *In vivo*, the TM domain forms a mixed disulfide with thioredoxin, and nDsbD forms a mixed disulfide with DsbC or CcmG. This demonstrates that DsbD utilizes at least two thiol-disulfide exchange reactions during the electron transfer from cytoplasmic thioredoxin to the periplasmic substrates. The direct reduction of DsbC by nDsbD was confirmed *in vitro* (Goldstone *et al.*, 2001). Studies on mixed disulfides combined with mutational analyses allowed the specification of DsbD cysteines involved in the reaction.

C163 of the TM domain forms a disulfide bond with C32 of thioredoxin, and C109 of nDsbD interacts with periplasmic substrate proteins. It was proposed that the catalytic mechanism of DsbD is exclusively based on inter- and intra-molecular disulfide exchange reactions. According to the existing model (Fig. 7), the TM domain accepts electrons from cytoplasmic thioredoxin and transfers them across the inner membrane to cDsbD, followed by successive reduction of nDsbD and finally of DsbC, DsbG or CcmG (Chung *et al.*, 2000; Katzen and Beckwith, 2000; Katzen *et al.*, 2002; Krupp *et al.*, 2001). It is likely that a significant conformational change takes place during the interconversions of oxidized and reduced forms of the TM domain (Katzen and Beckwith, 2003; Krupp *et al.*, 2001; Porat *et al.*, 2004), making the membrane-embedded cysteines alternatively accessible to the cytoplasm or to the periplasm. It is assumed that in the reduced state, the catalytic cysteines of the TM domain are accessible from the periplasm and available for interaction with oxidized cDsbD, while in the oxidized state, the disulfide bonds are accessible from the cytoplasm and interact with reduced thioredoxin (Katzen and Beckwith, 2003; Porat *et al.*, 2004).

Recently, crystal structures of both soluble periplasmic domains of DsbD and of the nDsbD-DsbC mixed disulfide complex were solved. The crystal structure of oxidized nDsbD revealed an immunoglobulin-like fold consisting of a β -sandwich formed by two antiparallel β -sheets and a catalytic subdomain that is inserted into the immunoglobulin-like fold (Fig. 8A) (Goulding *et al.*, 2002). In the oxidized form of nDsbD, the two active site cyteines form a disulfide bond between two β -strands. The active site disulfide is completely shielded from the environment by the active-site cap-loop region. Importantly, the nDsbD-SS-DsbC complex exhibits a stoichiometry of one nDsbD monomer per DsbC homodimer (Fig. 8B) (Haebel *et al.*, 2002). This is due to the fact that nDsbD binds into the central cleft of the V-shaped DsbC dimer and forms specific contacts with both catalytic domains of DsbC. Comparison of the complex with oxidized nDsbD revealed large conformational changes in the cap structure that regulates the accessibility of the nDsbD active site. In addition, Haebel and coworkers proposed that nDsbD exploits changes in the charge distribution of the active site to distinguish between oxidized and reduced forms of DsbC. cDsbD is a thioredoxin-like protein with a C-V-A-C active site motif. It possesses a thioredoxin fold and shares 28% sequence identity with thioredoxin. cDsbD consists of six α -helices and 4 β -strands, with an extended N-terminal stretch (Fig. 8C) (Kim *et al.*, 2003). This N-terminal stretch might serve as a flexible linker between the TM domain and cDsbD, allowing physical movement of cDsbD during electron shuttling.

Figure 8. Crystal structures of nDsbD (A), nDsbD-SS-DsbC complex (B), and cDsbD (C). nDsbD is depicted in red. The N-terminal dimerization domain and the C-terminal catalytic domain of DsbC are in pink and green, respectively. cDsbD is depicted in cyan. Active site cysteine residues are shown in yellow. (Goulding *et al.*, 2002; Haebel *et al.*, 2002; Kim *et al.*, 2003)

2.5.6 DsbG is a homologue of DsbC

DsbG is another periplasmic substrate of DsbD (Bessette *et al.*, 1999; Chung *et al.*, 2000). It was recently discovered on the basis of its ability to confer resistance to high concentrations of DTT, when encoded by a multicopy plasmid (Andersen *et al.*, 1997). DsbG is the least abundant of the periplasmic Dsb proteins (Bessette *et al.*, 1999). DsbG is a homodimeric protein that shows 28% sequence identity and 56% sequence similarity to DsbC (Andersen *et al.*, 1997; McCarthy *et al.*, 2000). The redox potentials of DsbC (−140 mV) and DsbG (−129 mV) are also similar (Bessette *et al.*, 1999; Rozhkova *et al.*, 2004; van Straaten *et al.*, 1998; Zapun *et al.*, 1995). Based on *in vivo* and *in vitro* data, it was proposed that DsbG has disulfide isomerase and chaperone activities (Bessette *et al.*, 1999; Shao *et al.*, 2000). Bessette

and colleagues showed that overexpression of DsbG can partially rescue the formation of multidisulfide proteins in a *dsbC* mutant background. However, DsbG was inactive in the classical insulin-reduction assay and, unlike DsbC, it does not catalyze oxidative refolding of RNaseA (Bessette *et al.*, 1999). Moreover, in contrast to DsbC, no *in vivo* substrates of DsbG were found (Hiniker and Bardwell, 2004). These findings suggest that DsbG is a specialized disulfide isomerase with considerably different substrate specificity compared to DsbC. Comparison of the recently solved structure of DsbG (Heras *et al.*, 2004) with the structure of DsbC (McCarthy *et al.*, 2000) offered clues to the differing substrate specificity of DsbG and DsbC. The uncharged surface of the DsbC cleft is consistent with binding of unfolded proteins. In contrast, the size and surface charge of the DsbG binding sites indicate that its substrates are likely to be much larger than those of DsbC and that they could be partially or completely folded.

2.6 The *Escherichia coli* thioredoxin system

The thioredoxin system supplies a variety of substrate proteins both in the cytosol and in the periplasm with reducing power (Holmgren, 1985). It is composed of cytosolic thioredoxin, thioredoxin reductase, and NADPH. Thioredoxin is a ubiquitous disulfide reductase responsible for maintaining proteins in their reduced state (Holmgren, 1985). It was first discovered as a hydrogen donor for ribonucleotide reductase (Laurent *et al.*, 1964), but later recognized as a general protein disulfide reductase that contributes to the cellular thiol-disulfide equilibrium (Derman *et al.*, 1993; Holmgren, 1985; Russel and Model, 1986). In the periplasm of *E. coli*, two different systems depend on the reducing potential of thioredoxin: disulfide bond isomerization and cytochrome *c* maturation pathways (Bolhuis *et al.*, 1999; Fabianek *et al.*, 1999; Krupp *et al.*, 2001; Missiakas *et al.*, 1995; Rietsch *et al.*, 1997; Stewart *et al.*, 1999). Upon reduction of a target protein, thioredoxin becomes oxidized and its reduced form is regenerated by thioredoxin reductase. Thioredoxin reductase is a dimeric FAD-containing enzyme that catalyzes the NADPH-dependent reduction of thioredoxin (for a review see (Williams, 1995)). The enzymatic mechanism of the thioredoxin system involves the transfer of electrons from NADPH via a system of redox-active disulfides. Electrons flow from NADPH to FAD, then to the active site disulfide of thioredoxin reductase, and finally to thioredoxin (for reviews see (Holmgren, 1985; Williams, 1995)). *In vitro*, reduction of thioredoxin by NADPH is very efficiently catalysed by thioredoxin reductase with a k_{cat}/K_m value of about $10^7 \text{ M}^{-1}\text{s}^{-1}$ (Mossner *et al.*, 1999). As thioredoxin is mainly in the reduced state

in *E. coli* cells (Holmgren and Fagerstedt, 1982), it appears that NADPH-dependent reduction of thioredoxin is not rate-limiting for the catalytic cycle of thioredoxin *in vivo*.

2.7 Cytochrome *c* maturation

2.7.1 General

The *c*-type cytochromes are soluble or membrane-anchored electron transfer proteins that are components of various photosynthetic and/or respiratory chains in bacteria, mitochondria, and chloroplasts. A special feature of the *c*-type cytochromes is the covalent attachment of the vinyl side groups of heme *via* two thioether bonds to the cysteine residues of the conserved C-X-X-C-H motif in apocytochrome *c* (Sambongi *et al.*, 1996). In the bacterial *c*-type cytochromes, the heme domain is located on the outer side of the cytoplasmic membrane (Thony-Meyer *et al.*, 1994). Synthesis of both the apocytochrome and the heme occurs in the cytoplasm followed by their separate export across the cytoplasmic membrane (Page and Ferguson, 1990) and covalent attachment of heme to the polypeptide. The heme-iron and the cysteines in the heme-binding motif of apocytochrome must be reduced prior to heme ligation (Sambongi *et al.*, 1996). The overall post-translational process that leads to the formation of properly folded cytochrome *c* with one (or more) covalently attached heme is called cytochrome *c* maturation or biogenesis.

2.7.2 Cytochrome *c* maturation in *Escherichia coli*

In *E. coli*, *c*-type cytochromes are synthesized exclusively under anaerobic conditions, under which the expression of the *ccm* genes is induced (Choe and Reznikoff, 1993; Rabin and Stewart, 1993; Tanapongpipat *et al.*, 1998). Eight genes called *ccmABCDEFGHIH* are specifically required for cytochrome *c* maturation in *E. coli* (Grove *et al.*, 1996; Thony-Meyer *et al.*, 1995). In addition, it was shown that gene products of the general secretion pathway (Sec-system) and cellular redox control system (the thioredoxin system and Dsb proteins) contribute to efficient cytochrome *c* biogenesis (Crooke and Cole, 1995; Grove *et al.*, 1996; Metheringham *et al.*, 1995; Sambongi and Ferguson, 1994, 1996). Lack of DsbA, DsbB, or DsbD results in a cytochrome *c* negative phenotype (Crooke and Cole, 1995; Metheringham *et al.*, 1995; Metheringham *et al.*, 1996; Sambongi and Ferguson, 1994, 1996), underlining the importance of balanced redox conditions for cytochrome *c* biogenesis. Ccm proteins are believed to form a membrane protein complex that coordinates delivery and attachment of heme to apocytochromes (for a review, see (Thony-Meyer, 2000, 2002)). CcmA is a peripheral membrane protein with a well-conserved ATP binding cassette (Goldman *et al.*,

1997a; Goldman *et al.*, 1997b). CcmB, an integral membrane protein with six transmembrane helices, is believed to be a permease. CcmA and CcmB seem to be the subunits of an ABC transporter. CcmC is an integral membrane protein with six predicted transmembrane helices that catalyze covalent attachment of heme to CcmE (Ahuja and Thony-Meyer, 2003; Ren and Thony-Meyer, 2001; Schulz *et al.*, 1998). Formation of the heme-binding form of CcmE is significantly enhanced in the presence of the small integral membrane protein CcmD, which apparently stabilizes CcmE in the membrane and influences the interaction between CcmC and CcmE (Ahuja and Thony-Meyer, 2005; Schulz *et al.*, 1999). The subsequent heme transfer from the holo-CcmE intermediate to apocytochrome *c* involves further integral membrane proteins, CcmF and CcmH, and also the membrane-anchored thioredoxin-like reductase CcmG (Fabianek *et al.*, 1998, 2000; Reid *et al.*, 2001; Schulz *et al.*, 1999). Co-immunoprecipitation experiments revealed that CcmF interacts directly with CcmE and CcmH, but not with apocytochrome *c*. This is in agreement with the view that CcmF and CcmH form a heme lyase complex in which CcmH recruits the apocytochrome and CcmF recruits the heme moieties for ligation (Ren *et al.*, 2002). As the ligation occurs in the oxidizing environment of the periplasm, the heme-binding cysteines of apocytochromes are likely to be oxidized and must be re-reduced for heme attachment. Bacteria have evolved a specific reductive pathway that utilizes the reducing power of cytoplasmic NADPH for the reduction of apocytochromes. In *E. coli*, electrons originating from NADPH are thought to flow from DsbD *via* CcmG and CcmH to apocytochromes *c* (Chung *et al.*, 2000; Crooke and Cole, 1995; Fabianek *et al.*, 1998; Fabianek *et al.*, 1999; Reid *et al.*, 1998; Reid *et al.*, 2001; Sambongi and Ferguson, 1994).

2.7.3 CcmG is a specific reductase from *Escherichia coli*

CcmG is a 20 kDa periplasmic, membrane-anchored thioredoxin-like protein essential for cytochrome *c* maturation (Fabianek *et al.*, 1998; Page and Ferguson, 1997; Reid *et al.*, 1998). The hydrophilic C-terminal domain of CcmG contains a C-P-T-C active site motif and has a redox potential of about -210 mV (Li *et al.*, 2001). CcmG active site cysteine residues are important for cytochrome *c* maturation (Fabianek *et al.*, 1998). It has been shown that strains, expressing CcmG variants with one or both active site cysteine residues replaced by serine, produce strongly decreased amounts of holocytochrome *c*. The restoration of cytochrome *c* biogenesis was achieved by addition of thiol reductants to the medium. In contrast to various other bacterial oxidoreductases, CcmG does not show reductase activity in the classical insulin reduction assay, and its absence does not affect the activity of alkaline phosphatase,

suggesting that reductase activity of CcmG is highly specialized and limited to the pathway of cytochrome *c* maturation (Fabianek *et al.*, 1997; Monika *et al.*, 1997; Page and Ferguson, 1997).

The recently solved crystal structure of a CcmG homologue from *Bradyrhizobium japonicum* (Edeling *et al.*, 2002) revealed a thioredoxin fold with several distinguishing features essential for cytochrome *c* maturation (Fig. 9). One of these features is a characteristic groove formed by two inserts in the fold, the N-terminal β -hairpin-like structure and the central insert. It was

Figure 9. Crystal structure comparison of CcmG (A) and thioredoxin (B). The characteristic groove of CcmG, formed by the N-terminal β -hairpin-like structure (insert 1) and the central insert (insert 2), is depicted in pink. Active site cysteine residues are shown in yellow. (Edeling *et al.*, 2002)

shown that deletion of any of the two inserts suppresses cytochrome *c* formation (Edeling *et al.*, 2002; Edeling *et al.*, 2004). Another CcmG-specific feature is an unusually acidic active site of CcmG compared with those of other thioredoxin-like proteins. Several conserved acidic residues contribute to the negative charge and are required for efficient cytochrome *c* maturation (Edeling *et al.*, 2004).

2.7.4 DsbD-dependent reduction of apocytochromes in *Escherichia coli*

The reducing power required for cytochrome *c* maturation in the periplasm of *E. coli* comes from the cytoplasmic thioredoxin system *via* the inner membrane redox catalyst DsbD and the periplasmic reductase CcmG (Fig. 4). Indeed, genetic studies showed that in the absence of DsbD, thioredoxin or thioredoxin reductase, cytochrome *c* maturation is suppressed and CcmG accumulates in the oxidized state (Chung *et al.*, 2000; Crooke and Cole, 1995; Metheringham *et al.*, 1996; Reid *et al.*, 1998; Sambongi and Ferguson, 1994). Detection of

the mixed-disulfide intermediate between DsbD and CcmG *in vivo* (Katzen and Beckwith, 2000) is strong evidence in favour of direct electron transfer from DsbD to CcmG. The mechanism of further electron transfer from CcmG to apocytochromes is not yet established, and several models exist (Reid *et al.*, 2001). According to the first model, electrons sequentially flow from reduced CcmG to CcmH and then to apocytochromes (Monika *et al.*, 1997; Page *et al.*, 1998; Reid *et al.*, 2001). The observation that only the second (but not the first) cysteine in the C-X-X-C active site motif of CcmH is important for cytochrome *c* maturation led to another model for apocytochrome *c* reduction (Fabianek *et al.*, 1999). First, a disulfide bond of oxidized apocytochrome *c* is broken by a nucleophilic attack of the second CcmH active site thiol, leading to a mixed disulfide between apocytochrome *c* and CcmH. This disulfide is then resolved by reduced CcmG, resulting in CcmG oxidation and release of reduced apocytochrome *c* and CcmH. In the last step, DsbD regenerates reduced CcmG.

Accumulating data suggest that the role of CcmG in cytochrome *c* maturation is more complex than solely reduction of apocytochromes. It has been shown that CcmG active site cysteine mutants are still able to produce some holocytochrome *c*, whereas *ccmG*⁻ strains are completely defective in cytochrome *c* maturation even in the presence of reductants (Fabianek *et al.*, 1998; Fabianek *et al.*, 1999; Grove *et al.*, 1996; Reid *et al.*, 2001; Thony-Meyer *et al.*, 1995). These results led to the conclusion that, apart from the reduction of apocytochromes, CcmG might also be required for stabilization of one or several proteins involved in cytochrome *c* maturation (Fabianek *et al.*, 1998).

2.8 Aim of the thesis

This thesis was focused on the investigation of the catalytic mechanism of the inner membrane protein DsbD from *E. coli*. First, we addressed the issue of the intrinsic biophysical properties and reactivity of nDsbD and cDsbD, and of the kinetic parameters of disulfide exchange between nDsbD and the three DsbD substrate proteins, DsbC, DsbG, and CcmG.

The second step was to establish a protocol for the synthesis of nDsbD-SS-cDsbD and nDsbD-SS-CcmG mixed-disulfide complexes, which would allow their crystallization and structure determination. The kinetic and structural data should provide an insight into the adaptability of nDsbD to its very different binding partners.

The coexistence of the oxidative DsbA/B and the reductive DsbC/D pathways within the same periplasmic compartment raised the question of how the two pathways are kept separate. If barriers did not exist, there would be a futile cycle in which, for instance, DsbD

would reduce DsbA, or DsbB would oxidize DsbC. Therefore, we have undertaken a kinetic analysis of all disulfide exchange reactions that may occur between protein from the oxidative DsbA/B and the reductive DsbC/D pathways.

Finally, we were interested to obtain the structures of oxidized and reduced cDsbD and to compare them with the structure of cDsbD in the nDsbD-SS-cDsbD complex.

DsbD from *Escherichia coli* catalyzes the transport of electrons from cytoplasmic thioredoxin to the periplasmic disulfide isomerase DsbC. DsbD contains two periplasmically oriented domains at the N- and C-terminus (nDsbD and cDsbD) that are connected by a central transmembrane (TM) domain. Each domain contains a pair of cysteines that are essential for catalysis. Here, we show that Cys109 and Cys461 form a transient interdomain disulfide bond between nDsbD and cDsbD in the reaction cycle of DsbD. We solved the crystal structure of this catalytic intermediate at 2.85 Å resolution, which revealed large relative domain movements in DsbD as a consequence of a strong overlap between the surface areas of nDsbD that interact with DsbC and cDsbD. In addition, we have measured the kinetics of all functional and nonfunctional disulfide exchange reactions between redox-active, periplasmic proteins and protein domains from the oxidative DsbA/B and the reductive DsbC/D pathway. We show that both pathways are separated by large kinetic barriers for nonfunctional disulfide exchange between components from different pathways.

Introduction

Disulfide bonds are a typical post-translational modification of secretory proteins. In bacteria, disulfide bond formation occurs in the oxidizing environment of the periplasm and is catalyzed by redox enzymes of the Dsb family. Two types of reactions are primarily required for correct formation of disulfide bonds in proteins with multiple disulfide bonds: disulfide bond formation and disulfide bond isomerization (Ritz and Beckwith, 2001; Collet and Bardwell, 2002; Hiniker and Bardwell, 2003). Each of these reactions is linked with an independent electron transfer pathway in *Escherichia coli*. The pathway of disulfide bond formation involves the oxidation of reduced, newly translocated proteins by the periplasmic dithiol oxidase DsbA. DsbA belongs to the thioredoxin family and has a very reactive disulfide bond (active site: Cys-Pro-His-Cys), which is transferred randomly and extremely rapidly to reduced polypeptide substrates by disulfide exchange (Wunderlich *et al.*, 1993; Zapun and Creighton, 1994; Darby and Creighton, 1995). Polypeptide oxidation generates reduced DsbA, which is reoxidized by ubiquinone from the respiratory chain, a two-electron transfer reaction catalyzed by the inner membrane protein DsbB (Bardwell *et al.*, 1993; Dailey and Berg, 1993; Bader *et al.*, 2000; Grauschopf *et al.*, 2003). The reduced quinone (ubiquinol) is then reoxidized by molecular oxygen via terminal cytochrome oxidases (Bader *et al.*, 1999; Kobayashi and Ito, 1999). The pathway of disulfide isomerization copes with wrong disulfide bonds randomly introduced by DsbA. The disulfide isomerase DsbC, a homodimeric, periplasmic protein with the active site Cys-Gly-Tyr-Cys, attacks wrong disulfide bonds in scrambled polypeptide substrates, and catalyzes their rearrangement to the native conformation (Missiakas *et al.*, 1994; Zapun *et al.*, 1995; McCarthy *et al.*, 2000; Maskos *et al.*, 2003). Consequently, for being active as a catalyst, DsbC has to be kept in a reduced state in an otherwise oxidizing cellular compartment. This is achieved through a specific electron transfer cascade in which two electrons from cytoplasmic NADPH flow to cytoplasmic thioredoxin, then to the inner membrane protein DsbD, and then to periplasmic DsbC (Rietsch *et al.*, 1997; Chung *et al.*, 2000; Krupp *et al.*, 2001).

DsbD consists of 546 amino acids and is composed of a periplasmically oriented, N-terminal domain with immunoglobulin-like fold (nDsbD), a central transmembrane (TM) domain predicted to be composed of eight TM helices, and a C-terminal domain with thioredoxin fold (cDsbD) that is again oriented toward the periplasm (Gordon *et al.*, 2000). Each of the three domains contains one pair of invariant cysteines that are essential for electron transport from thioredoxin to DsbC (Stewart *et al.*, 1999). It was hence postulated that the catalytic mechanism of DsbD is exclusively based on disulfide exchange reactions between DsbD and its substrate proteins, and intramolecular disulfide interchange between

Disulfide exchange in DsbD: structural basis and kinetics
A Rozhkova *et al*

Figure 1 Proposed electron flow from reduced thioredoxin in the cytoplasm to oxidized, homodimeric DsbC in the periplasm via DsbD. According to this mechanism, electron transport occurs exclusively through intermolecular and intramolecular disulfide exchange. DsbD consists of an N-terminal domain (nDsbD, residues 1–143) and a C-terminal domain (cDsbD; residues 419–546), which are oriented toward the periplasm, and a central TM domain (residues 144–418). Numbered circles represent essential cysteine residues in the respective protein.

the three DsbD domains (Goldstone *et al*, 2001; Krupp *et al*, 2001; Collet *et al*, 2002; Katzen and Beckwith, 2003). According to this model, oxidizing equivalents are transferred from oxidized DsbC to the Cys103/Cys109 pair of nDsbD, then to Cys461/Cys464 of the cDsbD, followed by oxidation of the Cys163/Cys285 pair of the TM domain, which eventually oxidizes thioredoxin in the cytoplasm (Figure 1). Besides DsbC, the proteins DsbG and CcmG (DsbE) are further known *in vivo* substrates of DsbD that are kept in a reduced state in the periplasm. DsbG is a homodimeric homolog of DsbC (26% sequence identity) of unknown function (Andersen *et al*, 1997; van Straaten *et al*, 1998; Bessette *et al*, 1999), and CcmG is a membrane-anchored enzyme with thioredoxin fold that is required for cytochrome *c* biogenesis (Reid *et al*, 2001).

Available structural information on DsbD includes the X-ray structure of oxidized nDsbD and the X-ray structure of the mixed disulfide between the Cys103Ala variant of nDsbD and the Cys101Ser variant of DsbC (Goulding *et al*, 2002; Haebel *et al*, 2002). In addition, a crystal structure of oxidized cDsbD has been reported (Kim *et al*, 2003). Importantly, the nDsbD-SS-DsbC complex exhibits a stoichiometry of one nDsbD monomer per DsbC homodimer. This is due to the fact that nDsbD does not only interact with residues around the active site disulfide of a DsbC subunit, but forms specific, additional contacts with the second subunit in the DsbC dimer that prevent binding of a second nDsbD equivalent in a symmetry-related manner.

Several aspects of the above model for the DsbD cycle raise questions regarding the structure of DsbD. In particular, it is not obvious how two cysteines in the TM domain should suffice to transport electrons over a distance of about 60 Å (membrane thickness) via a 'disulfide ladder' from the cytoplasm to the periplasm. In addition, the cysteine residues that

are involved in intramolecular disulfide interchange between the three domains in DsbD have not yet been identified. Here, we show that Cys109 and Cys461 mediate disulfide interchange between nDsbD and cDsbD. In addition, we solved the crystal structure of the kinetically stabilized mixed disulfide between both domains. The mixed disulfide complex represents a trapped intermediate in the catalytic cycle of DsbD, and reveals that large domain movements must occur during catalysis of electron transfer. Moreover, we demonstrate that both the reduction of DsbC by nDsbD, and disulfide interchange between nDsbD and cDsbD are very rapid processes. Finally, we show that the DsbA/B and DsbC/D redox systems are separated by large kinetic barriers that appear exclusively caused by steric block of disulfide exchange.

Results

Physical properties of the isolated periplasmic domains nDsbD and cDsbD

We expressed and purified the isolated periplasmic domains of DsbD, nDsbD (residues 1–143 of mature DsbD), and a C-terminally (His)₆-tagged variant of cDsbD (residues 419–546). To test the intrinsic reactivity of the individual domains, we analyzed the kinetics of electron transfer from reduced cDsbD via oxidized nDsbD to oxidized DsbC by reversed-phase HPLC separation of acid-quenched reactions products (Figure 2A). We found that the overall reaction is very rapid at pH 7.0 and 25°C, and yields reduced DsbC, oxidized nDsbD, and oxidized cDsbD within about 500 s when low initial concentrations of 0.25 μM were used for all proteins (monomer concentration in the case of DsbC). No mixed disulfides between nDsbD and DsbC, or nDsbD and cDsbC were detected. This indicates that these mixed disulfides are kinetically unstable and dissociate very rapidly by intramolecular disulfide exchange. As a control, we showed that the reverse reaction is not observed (Figure 2B). In addition, we measured the redox potentials of cDsbD, nDsbD, and DsbC at pH 7.0 and 25°C in identical buffer conditions, and obtained values of −0.235, −0.232, and −0.140 V, respectively (Figure 2F). The redox potential of DsbC and the practically identical potentials of cDsbD and nDsbD are in good agreement with previous measurements (Zapun *et al*, 1995; Collet *et al*, 2002) and confirm that complete electron transfer from cDsbD to DsbC via nDsbD is thermodynamically driven.

We next measured the individual microscopic rate constants of electron transfer from cDsbD to nDsbD, and from nDsbD to DsbC. Figures 2C and D show that reduction of DsbC by nDsbD is extremely rapid ($3.9 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$), while intermolecular disulfide exchange between cDsbD and nDsbD is more than one order of magnitude slower. Thus, electron transfer between cDsbD and nDsbD is rate-limiting for the overall *in vitro* reaction according to the following scheme.

Figure 2 Kinetics of electron transport from cDsbD via nDsbD to DsbC at 25°C and pH 7.0. The reactions were acid-quenched after different incubation times, and products were separated on a C_{18} reverse-phase HPLC column. (A) DsbC_{ox}, nDsbD_{ox}, and cDsbD_{red} (0.25 μ M each) were mixed at a 1:1:1 ratio. Note that nDsbD_{ox} and nDsbD_{red} cannot be separated under these conditions. (B) No electron flow from DsbC_{red} to cDsbD_{ox} or nDsbD_{ox} is observed. (C) Reduction of DsbC_{ox} by nDsbD_{red}. Initial protein concentrations were 0.25 μ M. The solid line corresponds to a second-order fit, with a rate constant of $3.9 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$. The rate constant of the reverse reaction ($3.0 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$) was deduced from the equilibrium constant of 1300 for the reduction of DsbC by nDsbD. (D) Disulfide exchange kinetics between isolated nDsbD and cDsbD. nDsbD_{red} and cDsbD_{ox} (0.25 μ M each) were mixed, and the attainment of the equilibrium was fitted according to second-order kinetics for the forward and the reverse reaction with the program *Berkeley Madonna*. The obtained equilibrium constant of 1.4 agrees well with the calculated equilibrium constant of 1.3 from the redox potential measurements (see panel F). The fit (solid line) yielded rate constants of 1.1×10^5 and $7.9 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$ for the forward and reverse reactions, respectively. (E) Direct reduction of DsbC_{ox} by cDsbD_{red} in the absence of nDsbD. The reaction was performed under pseudo-first-order conditions, with initial concentrations of 1 μ M for DsbC_{ox} (monomer) and 10 μ M for cDsbD_{red}. The fit (solid line) yields a rate constant of $57 \text{ M}^{-1} \text{ s}^{-1}$. The rate constant for the reverse reaction was calculated from the equilibrium constant (1600) for the reduction of DsbC by cDsbD. (F) Determination of the redox potentials of nDsbD, cDsbD, and DsbC at pH 7.0 and 25°C by equilibration of proteins with thiol-disulfide redox buffers (see Materials and methods for details). All concentrations of DsbC refer to the DsbC monomer.

However, disulfide exchange between nDsbD and cDsbD is most likely not rate-limiting for the reaction cycle of intact DsbD, where nDsbD and cDsbD are covalently linked and thus expected to have very high effective concentrations. As an additional control, we showed that direct reduction of DsbC by cDsbD is almost five orders of magnitude slower ($k_2 = 57 \text{ M}^{-1} \text{ s}^{-1}$) compared to the reduction by nDsbD (Figures 2E and 6). This result explains why both periplasmic domains of DsbD are required for shuffling electrons from the TM domain of DsbD to DsbC.

Cys109 and Cys461 form a mixed disulfide between nDsbD and cDsbD

To identify the cysteine residues that form a transient mixed disulfide between nDsbD and cDsbD in the DsbD reaction cycle, we purified the single-cysteine variants Cys103Ser and Cys109Ser of nDsbD, and Cys461Ser and Cys464Ser of cDsbD. Free thiol groups in the purified proteins were quantified with Ellman's assay both at the level of the native and denatured states. Table 1 shows that only Cys109 of nDsbD and Cys461 of cDsbD are reactive and solvent accessible, while Cys103

Disulfide exchange in DsbD: structural basis and kineticsA Rozhkova *et al*

and Cys464 are buried in the folded domains. Consequently, disulfide exchange between nDsbD and cDsbD can only occur via a transient disulfide bond between Cys109 and Cys461. To prepare a kinetically stable mixed disulfide between nDsbD and cDsbD, we first synthesized the activated mixed disulfide between nDsbD-C103S and thionitrobenzoic acid by incubation of nDsbD-C103S with excess of Ellman's reagent. The activated mixed disulfide was then purified and mixed with equimolar amounts of the variant cDsbD-C464S, which resulted in almost quantitative formation of the mixed disulfide between nDsbD-C103S and cDsbD-C464S (Supplementary Figure S1). The reaction product was purified to homogeneity by chromatography on Ni-NTA agarose and gel filtration, concentrated to 40 mg/ml, and crystallized.

Structure determination of the mixed disulfide between nDsbD and cDsbD

The X-ray structure of the mixed disulfide between nDsbD and cDsbD (termed nDsbD-SS-cDsbD in the following) was

solved at a resolution of 2.85 Å (PDB entry 1SE1). The crystals belong to space group C2 and contain three nDsbD-SS-cDsbD complexes (A–C) per asymmetric unit. The structure reveals in full detail how the N-terminal immunoglobulin-like domain of DsbD interacts with the C-terminal thioredoxin-like domain.

The final electron density map is well defined throughout the structure, which was refined to an *R*-factor of 0.224 and a free *R*-factor of 0.284 (Table II). The Ramachandran plot statistics is very good (Table II) with only one residue (Asp79 from nDsbD) in the disallowed region. The electron density of Asp79 is well defined and was found to be identical in the structure of noncomplexed nDsbD (Goulding *et al* (2002), PDB entry 1L6P (1.65 Å), Haebel *et al* (2002), PDB entry 1JPE (1.9 Å)) and for the complex between nDsbD and DsbC (nDsbD-SS-DsbC, Haebel *et al* (2002), PDB entry 1JZD (2.3 Å)), respectively.

The average *B*-factor for the final nDsbD-SS-cDsbD model is 38.4 Å², which compares with a Wilson *B*-factor of 68.8 Å² for the data and with an average *B*-factor of 43.3 Å² for the structure of nDsbD-SS-DsbC (PDB entry 1JZD).

Overall structure of nDsbD-SS-cDsbD

nDsbD possesses an immunoglobulin-like fold (Goulding *et al*, 2002), and cDsbD a thioredoxin-like fold (Kim *et al*, 2003). Each nDsbD-SS-cDsbD complex has dimensions of about 34 Å × 43 Å × 75 Å (Figure 3A). Comparison of the nDsbD-SS-DsbC complex with nDsbD-SS-cDsbD reveals similarities and differences in the binding mode and interfaces. As Cys109 of nDsbD forms a mixed disulfide with the solvent-exposed, nucleophilic cysteine of its reaction partner in both

Figure 3 (A) Ribbon diagram of the structure of the nDsbD-SS-cDsbD mixed disulfide. The structure of nDsbD (red) comprises residues 1–125, and that of cDsbD (blue) residues 426–545 (complex B). The disulfide bond between Cys109 and Cys461 is depicted in yellow. (B) Superposition of the C^α-traces of nDsbD from the nDsbD-SS-DsbC complex (1JZD, green) and nDsbD from nDsbD-SS-cDsbD (complex B, blue) onto that of monomeric nDsbD (1L6P, red) shows different conformations of the Cap-loop region (residues 68–72). (C) Stereo picture showing differences in the orientation of cDsbD (blue) and DsbC (green) in the complex with nDsbD (not shown), based on superposition of nDsbD from nDsbD-SS-DsbC (1JZD) onto nDsbD from the nDsbD-SS-cDsbD complex. The arrow indicates the approximate position of the active site cysteines for both complexes.

complexes, the contact areas of nDsbD for binding of cDsbD and DsbC overlap. Cys109 in isolated oxidized nDsbD is shielded by the so-called Cap-loop region (segment Asp68–Gly72) (Goulding *et al*, 2002). As reported for the nDsbD-SS-DsbC complex (Haebel *et al*, 2002), Cys109 of nDsbD becomes accessible in nDsbD-SS-cDsbD due to a conformational switch of that region. The Cap-loop region is in a more open conformation in nDsbD-SS-cDsbD than in the nDsbD-SS-DsbC complex (Figure 3B). Crystal contacts between nDsbD-SS-nDsbD complexes A and C may contribute to this difference. In the case of complex B, the Cap-loop

region is involved only in a weak crystal contact with complex A through a hydrogen bond. Electron density for residues Phe70 and Tyr71 (side chain only) in complex B is poorly defined, indicating that the Cap-loop region is flexible.

Kim *et al* (2003) previously modelled the nDsbD-SS-cDsbD complex using the nDsbD-SS-DsbC structure (Haebel *et al*, 2002) as a template. However, the orientation of cDsbD relative to nDsbD in the experimental structure of nDsbD-SS-cDsbD differs from this model (Figure 3C). For example, helix α 2a and strand β 2 of cDsbD have a different orientation (an angle of $\sim 20^\circ$) than the corresponding helix α 3 and strand β 8 of DsbC in the model.

The three copies of the nDsbD domain in the asymmetric unit also exhibit differences around the N-termini due to crystal contacts. In complex A, electron density is visible for residues Gly1 to Ala5, then there is a gap until Gln10. In complex B, the entire N-terminal region has well-defined electron density, whereas no clear electron density is discernible before Ser9 in complex C. These N-terminal residues in complexes A and B adopt different conformations, which again appear to be caused by crystal contacts.

A surface representation of nDsbD-SS-cDsbD shows a relatively planar region between the C-terminus of nDsbD and the N-terminus of cDsbD, which is supposed to be oriented towards the surface of the membrane (Supplementary Figure S2). The TM domain of DsbD consists of eight predicted TM helices (Stewart *et al*, 1999; Chung *et al*, 2000; Gordon *et al*, 2000). Recently, Katzen and Beckwith (2003) showed that Cys163 from the first predicted TM helix 1 can form a disulfide bridge with Cys285 from the fourth TM helix, and proposed a model for the TM domain in which helices 1 and 8 are adjacent. This model would require long linker segments to connect the TM domain with the crystallographically observed C-terminus of nDsbD and N-terminus of cDsbD, which are approximately 60 Å apart. The 20 residues separating the last observed residue of nDsbD from the first predicted residue of TM helix 1, and the 15 residues between the last residue of the predicted TM helix 8 and the first observed residue of cDsbD may span this distance. Comparison of the structure of nDsbD-SS-cDsbD with that of nDsbD-SS-DsbC suggests that a large translation of nDsbD away from cDsbD is required to allow disulfide exchange of nDsbD in the context of full-length DsbD with the active site of DsbC. In addition, there may be a rotation of nDsbD such that Cys109 is sufficiently distant from the plane of the membrane to prevent clashes between DsbD and DsbC (Figure 4).

Specific interactions stabilizing the nDsbD-SS-cDsbD complex

Besides the interdomain disulfide bond, the nDsbD-SS-cDsbD domain interface is characterized by only a limited number of specific interactions, namely four (complex B), five (complex C), or six (complex A) interdomain hydrogen bonds (Table III). The main-chain carbonyl of Cys109 is hydrogen-bonded to the amide nitrogen of Leu510, and the amide nitrogen of Cys109 is linked to the carbonyl oxygen of Leu510. A third hydrogen bond near the active cysteines is formed by the amide nitrogen of Phe531 and by the carbonyl of Gly107. The other interdomain hydrogen bonds lie in the Cap-loop region and differ in every complex in the asymmetric unit due to conformational changes induced by crystal contacts. In complexes A and C, the side-chain amine of

Disulfide exchange in DsbD: structural basis and kinetics

A Rozhkova *et al*

Lys469 and the hydroxyl group of Tyr470 are involved in a network of hydrogen bonds with the carboxylate of Glu69. In complexes A and B, the hydroxyl group of Tyr71 also interacts with the main-chain carbonyl of Asp459, while the electron density of Tyr71 in complex B is not well defined. Overall, the number of specific contacts is rather limited relative to the size of the interface area (1301 Å², see below).

Comparison between the contact interface of nDsbD-SS-cDsbD and nDsbD-SS-DsbC

We calculated the interface areas of nDsbD-SS-cDsbD and nDsbD-SS-DsbC with the program Grasp (Nicholls *et al*, 1993) following the protocol of Janin (1997). nDsbD-SS-cDsbD has a calculated binding interface of 1301 Å², whereas nDsbD-SS-DsbC has an interface of 2045 Å² (Figure 5, Table III). This difference is caused by the second nDsbD interface in the nDsbD-SS-DsbC complex, which mediates additional noncovalent contacts between nDsbD and the second DsbC subunit.

The first interface of nDsbD-SS-DsbC is the active site interface; this interface strongly overlaps with the interface

Figure 4 Electron transfer from cDsbD to DsbC via nDsbD involves large domain movements. Left: Proposed orientation of nDsbD-SS-cDsbD with respect to the transmembrane domain (TMD) in the context of full-length DsbD. Cys163 and Cys285 from the TM domain are indicated by yellow circles, and sulfur atoms of Cys109 and Cys461 are depicted by yellow spheres. The 20- and 15-residue-long linkers connecting the last structured residue of nDsbD with the first predicted TMD residue, and the last predicted TMD residue with the first structured residue of cDsbD, respectively, are indicated as black lines. Right: Model of the mixed disulfide complex between DsbD and DsbC, based on the structures of nDsbD-SS-cDsbD and nDsbD-SS-DsbC (1JZD). Disulfide exchange between nDsbD and DsbC is only possible when nDsbD and cDsbD undergo a massive domain movement.

of nDsbD-SS-cDsbD (Figure 5) and has a comparable size of 1376 Å². In fact, the nDsbD-SS-cDsbD and the nDsbD-SS-DsbC interfaces share a common area of around 90% of their surface. Similarly to the interface between nDsbD and cDsbD (4–6 interdomain hydrogen bonds), also in the nDsbD-SS-DsbC complex there is only a limited number (7) of inter-subunit hydrogen bonds (Table III). Three hydrogen bonds described for nDsbD-SS-cDsbD are located at the same position as in nDsbD-SS-DsbC. The main-chain carbonyl and the amide nitrogen of Cys109 (nDsbD) hydrogen-bond the amide nitrogen and carbonyl oxygen, respectively, of Thr182 of DsbC. The third hydrogen bond is formed by the amide nitrogen of DsbC Tyr196 and by the carbonyl of Gly107 (nDsbD).

The nDsbD-SS-DsbC complex has one residue forming intersubunit hydrogen bonds in the Cap-loop region (hydroxyl group of Tyr71 of nDsbD to the guanidinium moiety of DsbC Arg125). As mentioned above, the Cap-loop region in the nDsbD-SS-cDsbD complex is also involved in crystal contacts. In nDsbD-SS-cDsbD, the Cap-loop region exhibits a wider opening than in nDsbD-SS-DsbC.

The additional, second interface of nDsbD-SS-DsbC is stabilized by three hydrogen bonds and a specific salt bridge. Indices for planarity and shape complementarities (sc-index) were also calculated. Lower planarity and a lower sc-index are found for nDsbD-SS-cDsbD (Table III). The planarity for nDsbD-SS-cDsbD is 1.81 Å and for nDsbD-SS-DsbC 2.34 Å (first interface). Analysis of 23 optional interfaces of protein–protein complexes by Jones and Thornton (1996) updated at http://www.biochem.ucl.ac.uk/bsm/-PP/server/server_datasets.html yielded an average planarity of 2.6 Å ($\sigma = 0.6$ Å). Compared to this value, nDsbD-SS-cDsbD shows a very low planarity, whereas nDsbD-SS-DsbC shows a value that lies in the average. Comparison of these values, the wider opening of the Cap-loop region and the additional contact area in nDsbD-SS-DsbC suggest that the interaction of nDsbD with cDsbD may be less specific than that with DsbC. This is, however, most likely compensated by the high relative effective concentrations of the periplasmic domains in the context of full-length DsbD.

Large kinetic barriers guarantee the coexistence of the DsbA/B and DsbC/D redox system

We measured the rate constants of nonfunctional disulfide exchange reactions either by tryptophan fluorescence (DsbA/DsbC, DsbA/nDsbD, DsbA/cDsbD, DsbB/DsbC) or acid-quenching after different reaction times and HPLC separation of reaction products (nDsbD/DsbC, cDsbD/DsbC). Figure 6 shows that all nonfunctional disulfide exchange reactions are

indeed 10^3 – 10^7 -fold slower than disulfide exchange between DsbA and DsbB, and DsbC and nDsbD, both of which have apparent second-order rate constants above $10^6 \text{ M}^{-1} \text{ s}^{-1}$ at pH 7.0. Among the nonfunctional reactions, oxidation of DsbC by quinone-depleted DsbB is fastest ($1.9 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$), albeit >1000-fold slower than oxidation of DsbA by DsbB (Figure 6). This explains that DsbC accumulates in the oxidized form in the periplasm of *dsbD* null strains (Rietsch *et al*, 1997) and indicates that DsbC may be oxidized directly by DsbB in these strains. Conversely, DsbA is also a very poor redox partner of DsbD ($k_{\text{app}} = 900 \text{ M}^{-1} \text{ s}^{-1}$), again in agreement with the predominantly reduced state of DsbA in *dsbB* deletion mutants (Kishigami *et al*, 1995). Overall, the kinetic data demonstrate that large kinetic barriers for nonfunctional disulfide exchange reactions guarantee the coexistence of the DsbA/B and DsbC/D redox systems.

Conclusions

In the present work, we have gained a complete picture on the kinetics of disulfide exchange reactions that may occur between proteins from the oxidative DsbA/B and reductive DsbC/D pathway in the *E. coli* periplasm. Overall, nonfunctional reactions between oxidoreductase components from different pathways are separated by large kinetic barriers from functional reactions, such that nonfunctional disulfide exchange is 10^3 – 10^7 times slower than functional electron transfer. Steric hindrance of nonfunctional interactions is likely to be the main mechanism guaranteeing the indepen-

dence of the DsbA/B and DsbC/D systems. An alternative explanation would be particularly fast, functional disulfide exchange reactions mediated through very specific side-chain contacts in the contact area between functional reaction partners. We consider this mechanism less prevalent. This is best illustrated by nDsbD, which not only interacts rapidly with cDsbD and DsbC (Katzen and Beckwith, 2000; Krupp *et al*, 2001; Collet *et al*, 2002) via its nucleophilic Cys109 thiol, but is also supposed to react rapidly with DsbG (Bessette *et al*, 1999) and CcmG (Katzen *et al*, 2002) via Cys109. It is thus difficult to conceive a single binding area around Cys109 in nDsbD that simultaneously mediates highly specific recognition of four different target proteins. Indeed, the number of specific hydrogen bonds and salt bridges in the interface between nDsbD and cDsbD relative to the total binding area of about 1300 \AA^2 is very small (Table III). The same holds true for the nDsbD-SS-DsbC complex, albeit there are additional contacts to the second DsbC subunit (Table III). We thus conclude that surface complementarity to the extent that disulfide interchange between active sites can occur without steric hindrance, and a limited number of specific contacts are sufficient to mediate rapid, functional disulfide exchange between intrinsically reactive Dsb proteins. A main factor determining the intrinsic reactivities of the nucleophilic active site cysteines in proteins from the thioredoxin family is the strongly lowered pK_a value of the more N-terminal active site thiols (Nelson and Creighton, 1994). For example, the pK_a values of the nucleophilic cysteines in DsbA and DsbC are 3.4 and 4.1, respectively (Nelson and Creighton, 1994; Sun

Disulfide exchange in DsbD: structural basis and kinetics

A Rozhkova *et al*

Figure 6 Large kinetic barriers separate the DsbA/B and DsbC/D redox systems. Apparent rate constants of disulfide exchange were measured at pH 7.0 and 25°C. Functional disulfide exchange reactions (bold solid arrows) have second-order rate constants above $10^6 \text{ M}^{-1} \text{ s}^{-1}$, while nonfunctional ('forbidden') reactions (dotted arrows) are 10^3 – 10^7 -fold slower. Arrows indicate the direction of two-electron transfer. All measured rates have errors <30%. ^{a)}Grauschopf *et al* (2003). ^{b)}Zapun *et al* (1995) reported a value of $100 \text{ M}^{-1} \text{ s}^{-1}$ for this reaction at pH 7.5. ^{c)}Reactions were followed by the change in tryptophan fluorescence.

and Wang, 2000), and are sufficient to explain the high reactivity of both proteins (Szajewski and Whitesides, 1980; Grauschopf *et al*, 1995; Huber-Wunderlich and Glockshuber, 1998).

We have shown that Cys109 from nDsbD and Cys461 from cDsbD form a transient mixed disulfide bond in the reaction mechanism of DsbD, and conclude that large relative domain movements between nDsbD and cDsbD are necessary to allow electrons flow from cDsbD to DsbC. The fact that nDsbD but not cDsbD can be cleaved off proteolytically from full-length DsbD (Collet *et al*, 2002) indicates that the linker segment between nDsbD and the TM domain is more flexible than that between cDsbD and the TM domain. It may therefore well be that it is essentially nDsbD that moves away from cDsbD to allow subsequent disulfide exchange between nDsbD and DsbC, DsbG, or CcmG.

If we assume that DsbD-mediated electron transfer occurs exclusively via disulfide exchange (Chung *et al*, 2000; Katzen and Beckwith, 2000; Krupp *et al*, 2001), the last mechanistic step that remains to be elucidated will be the identification of the pair of cysteines that mediate disulfide exchange between the TM domain and cDsbD. As Cys461 is the only surface-exposed residue in cDsbD, we propose that Cys461 not only reacts with Cys109 of nDsbD, but is also capable of forming a disulfide bond with either Cys163 or Cys285 from the TM domain if this mechanism holds true. This implies additional domain movements of cDsbD relative to the TM domain. Cys163 and Cys285 are both located in the predicted TM helices 1 and 4, can form a disulfide bond that connects both helices, and have been shown to be accessible from the cytoplasmic side (Chung *et al*, 2000; Katzen and Beckwith, 2003). This has led to a model according to which the TM domain of DsbD adopts a 'funnel-like' structure, with the 'funnel' opening toward the cytoplasm when the Cys163–Cys285 disulfide is formed (Katzen and Beckwith, 2003). Direct oxidation of the Cys163–Cys285 pair by oxidized

cDsbD is thus only conceivable when a major structural rearrangement occurs in the TM domain such that the 'funnel' opens toward the periplasm when the Cys163–Cys285 disulfide is reduced by cytoplasmic thioredoxin. Alternatively, a protein-bound cofactor may assist electron transfer from the Cys163/Cys285 pair to the Cys461–Cys464 disulfide bond of cDsbD.

Materials and methods

Construction of expression plasmids

The plasmid pNDsbD for cytosolic expression of nDsbD (residues 1–143 of mature DsbD) under control of *trc*-promotor/*lac*-operator was constructed as follows. A 435-bp gene fragment encoding nDsbD was amplified by PCR from genomic DNA of the *E. coli* wild-type strain W3110 with primers N1 (5'-GGG AAT TCC ATA TGA TGG CTC AAC GCA TCT TTA CG-3') and N2 (5'-CCC GGA TCC TTA TTG CCG GGT GGG CTG C-3') and cloned into pDsbA3 (Hennecke *et al*, 1999) via *Nde*I and *Bam*HI.

For expression of cDsbD (residues 419–546 of mature DsbD) with C-terminal (His)₆ tag, a 399-bp fragment was amplified with primers C1 (5'-CTA GCT AGC CAG GAT TGG GCA TTT GGT GCG ACG C-3') and C2 (5'-CGC GGA TCC TTA ATG GTG ATG GTG ATG GTG CCG TTG GCG ATC GCG C-3') and cloned into pDsbA3 via *Nhe*I and *Bam*HI. In the resulting plasmid pCDsbD, the sequence encoding (His)₆-tagged cDsbD is fused to the DsbA signal sequence for periplasmic expression under the control of *trc*-promotor/*lac*-operator.

The Cys variants of nDsbD and cDsbD, in which one of the active site cysteines was replaced by a serine, were constructed from pNDsbD and pCDsbD using the QuikChange method (Stratagene). All constructs were verified by DNA sequencing.

Purification of nDsbD, cDsbD, DsbA, DsbB, and DsbC

All proteins were expressed in the *E. coli* BL21-Rosetta cells (Novagene) grown in 9l of Luria-Bertani (LB) medium containing ampicillin (100 µg/ml) at 37°C. Protein production was induced with IPTG (final concentration 100 µM) when cells had reached an optical density (OD) at 600 nm of 0.6–0.8. After further growth at 37°C for 4 h, bacteria were harvested by centrifugation.

For purification of nDsbD, cells were suspended in 5 mM Tris-HCl (pH 8.0) and disrupted (Cell Cracker). After centrifugation at

Disulfide exchange in DsbD: structural basis and kinetics

A Rozhkova *et al*

50 000g for 30 min at 4°C, the supernatant was dialyzed at 4°C against 5 mM Tris-HCl (pH 8.0), and applied on Fast Flow Q Sepharose pre-equilibrated with the same buffer. Proteins were eluted with a gradient of 0 to 500 mM NaCl in 5 mM Tris-HCl (pH 8.0). Fractions containing nDsbD were pooled and mixed with ammonium sulfate to a final concentration of 1.4 M. The solution was applied to Phenyl Sepharose HP equilibrated with 1.4 M ammonium sulfate and 10 mM Tris-HCl (pH 8.0). Proteins were eluted with a gradient from 1.4 to 0 M ammonium sulfate in 10 mM Tris-HCl (pH 8.0). Fractions containing pure nDsbD were dialyzed against distilled water. The final yield of purified nDsbD was 100 mg/l bacterial culture.

For purification of cDsbD, bacteria were suspended in cold PBS buffer (20 mM sodium phosphate (pH 7.5), 150 mM NaCl) containing polymyxin B (1 mg/ml) and shaken at 4°C for 90 min. After centrifugation at 50 000g for 30 min at 4°C, the supernatant was mixed with imidazole-HCl (pH 7.5) to a concentration of 10 mM and applied to a Ni-NTA Superflow column equilibrated with 10 mM imidazole-HCl and PBS (pH 7.5). Proteins were eluted with a gradient from 10 to 300 mM imidazole-HCl in PBS. Fractions containing (His)₆-tagged cDsbD were dialyzed against distilled water. The final yield of purified protein was 20 mg/l bacterial culture.

Cysteine variants of nDsbD and (His)₆-tagged cDsbD were purified according to the same protocols with comparable yields. Oxidized *E. coli* DsbA (Hennecke *et al*, 1999), oxidized *E. coli* DsbC (Maskos *et al*, 2003), and oxidized, quinone-depleted *E. coli* DsbB (Grauschopf *et al*, 2003) were purified as described.

Synthesis of nDsbD-SS-cDsbD

For preparation of nDsbD-SS-cDsbD, we first prepared the mixed disulfide between the nDsbD variant C103S and nitrothiobenzoic acid (nDsbD(C103S)-NTB). The variant C103 was produced in *E. coli* and enriched by chromatography on Fast Flow Q Sepharose as described for wild-type nDsbD. Pooled fractions (in Tris-HCl (pH 8.0)) were mixed with excess dithiobisnitrobenzoic acid (DTNB) (final concentration 10 mM) and incubated at 25°C for 15 min. After addition of ammonium sulfate to a concentration of 1.2 M, the solution was applied to Phenyl Sepharose HP equilibrated with 1.2 M ammonium sulfate and 10 mM Tris-HCl (pH 8.0). The mixed disulfide was eluted with a gradient from 1.2 to 1 M ammonium sulfate. Fractions containing nDsbD(C103S)-NTB were pooled and dialyzed against PBS (pH 7.5). The (His)₆-tagged variant C464S of cDsbD was purified from the periplasmic extract as described for (His)₆-tagged wild-type cDsbD, and also dialyzed against PBS (pH 7.5).

Purified nDsbD(C103S)-NTB and cDsbD(C464S) were then mixed at equimolar concentrations (30 μM each), incubated in PBS for 30 min at 25°C, and applied to a Ni-NTA Superflow column equilibrated with PBS (pH 7.5). The column was washed with PBS and 10 mM imidazole-HCl (pH 7.5), and the nDsbD(C103S)-cDsbD(C464S) mixed disulfide (nDsbD-SS-cDsbD) was eluted with a gradient from 10 to 70 mM imidazole-HCl. Fractions containing the mixed disulfide and small amounts of cDsbD were concentrated and subjected to gel filtration on a Superdex 75 16/60 column in 100 mM sodium phosphate and 500 mM NaCl (pH 7.0). Fractions containing the pure complex were dialyzed against distilled water and concentrated.

Protein concentrations

Protein concentrations were determined according to the molar extinction coefficients at 280 nm, using values of 20 000 and 8300 M⁻¹ cm⁻¹ for native nDsbD and native cDsbD, respectively. For oxidized DsbA, DsbC, and DsbB, extinction coefficients of 23 250, 16 200, and 47 750 M⁻¹ cm⁻¹ were used, respectively. Reduced proteins were prepared by reduction with a 1000-fold molar excess of DTT at pH 8.0, followed by gel filtration in 0.1 mM EDTA. Free thiol groups in reduced proteins were quantified by Ellman's assay (Ellman, 1959) using $\epsilon_{412\text{nm}} = 13\,600\text{ M}^{-1}\text{ cm}^{-1}$ per free thiol group.

HPLC analysis of disulfide exchange kinetics

Disulfide exchange reactions between Dsb proteins were performed at 25°C and initial protein concentrations between 0.25 and 75 μM under second-order or pseudo-first-order conditions in 100 mM sodium phosphate and 0.1 mM EDTA (pH 7.0). Samples were removed after different incubation times, and the reactions were

rapidly quenched by addition of 0.4 volumes of 30% (w/v) formic acid (final pH < 2). Reaction products were separated with an Agilent 1100 HPLC instrument equipped with a diode array detection system and a C₁₈ reverse-phase column (Agilent Zorbax 300 SB, 5 μM, 2.1 × 150 mm). Proteins were eluted at 55°C with a linear gradient of H₂O/0.1% TFA and acetonitrile/0.07% TFA, and detected by their absorbance at 220 and 280 nm.

Fluorescence measurements

Disulfide exchange between DsbC_{red} and DsbB_{ox}, and between nDsbD_{red} (or cDsbD_{red}) and DsbA_{ox} was followed by the change in tryptophan fluorescence at 330 nm (excitation at 280 nm) in 100 mM sodium phosphate and 0.1 mM EDTA (pH 7.0). Initial protein concentrations varied between 5 and 50 μM for the individual reactions.

Redox equilibria

For determination of equilibrium constants (K_{eq}) between Dsb proteins and glutathione or DTT (cf. Grauschopf *et al*, 2003 and references cited therein), the redox state of the respective protein at different [GSH]²/[GSSG] or DTT_{ox}/DTT_{red} ratios was determined. Proteins were incubated for 16 h at 25°C in 100 mM sodium phosphate and 0.1 mM EDTA (pH 7.0) containing the respective thiol-disulfide mixtures. In the case of nDsbD, the fraction of reduced protein was quantified by Ellman's assay after removal of excess DTT through gel filtration. In the case of cDsbD and DsbC, the oxidized and reduced forms of the protein were separated and quantified by reverse-phase HPLC after acid quenching. cDsbD and nDsbD were equilibrated with DTT_{ox}/DTT_{red} mixtures, while DsbC was incubated with glutathione redox buffers. To exclude air oxidation, all buffers were degassed and flushed with argon. Standard redox potentials (E_o') were calculated by the Nernst equation ($E_o'_{\text{protein}} = E_o'_{\text{reference}} - (RT/2F) \ln K_{\text{eq}}$), using E_o' values of -0.240 and -0.307 V for the redox potentials of glutathione and DTT_{ox}/DTT_{red}, respectively (Rost and Rapoport, 1964; Rothwarf and Scheraga, 1992).

Crystallization and structure determination

Purified disulfide-linked nDsbD-SS-cDsbD complex in distilled water was concentrated to 40 mg/ml. The sitting drop vapor diffusion method was used for producing crystals. A measure of 1 μl of protein solution was mixed with 1 μl of mother liquor solution (0.1 M sodium acetate (pH 4.5), 0.8 M sodium formate, 25% PEG 2K MME). Plate-like crystals grew at 4°C within a week to maximum dimensions of 130 × 500 × 30 μm. Crystals were cryoprotected by adding 15% ethylene glycol to the mother liquor solution and directly frozen in the nitrogen gas stream. Diffraction data were collected at 98.2 K on beamline X06SA at the Swiss Light Source (Paul Scherrer Institut Villigen, Switzerland) using a MAR CCD image plate at a wavelength of 0.7514 Å. The short wavelength was chosen to reduce synchrotron radiation damage to the disulfide bridge (Schlichting *et al*, 2000). Data were processed with DENZO and SCALEPACK (Otwinowski and Minor, 1997) to 2.85 Å. nDsbD-SS-cDsbD crystals belong to space group C2 with $a = 188.5\text{ Å}$, $b = 52.6\text{ Å}$, $c = 107.9\text{ Å}$, and $\beta = 100.4^\circ$, and contain three molecules per asymmetric unit (Table II).

The structure of nDsbD-SS-cDsbD was solved by molecular replacement with AMoRe (Navaza, 1994) using the structure of nDsbD from the nDsbD-SS-DsbC structure (PDB entry 1JZD; Haebel *et al*, 2002) and a high-resolution structure of cDsbD (G Capitani and Ch U Stirnimann, unpublished data) as search models, against 12–4 Å data. Solutions for two complexes could be found using AMoRe against the data processed in C2. This corresponds to four solutions against data processed in P1. These four P1 solutions were refined in CNS (Brünger *et al*, 1998) to an R -factor of 0.418 and a free R -factor of 0.426. Nine cycles of water picking (with ARP/wARP-like picking parameters) and density modification in CNS lead to a much improved map, which was skeletonized with MAPMAN (Kleywegt and Jones, 1996). The waters introduced in the previous phase improvement step were then deleted. The structure refined to an R -factor of 0.308 and a free R -factor of 0.348 after having fitted the fifth and sixth complexes to the skeleton and to the density by hand using the program O (Jones *et al*, 1991). Molecular replacement in AMoRe worked now in C2 by picking the three corresponding P1 solutions. The nDsbD-SS-cDsbD structure was iteratively rebuilt in O and refined in CNS using NCS restraints to an R -factor of 0.224 and a free R -factor of 0.284 in space group C2

Disulfide exchange in DsbD: structural basis and kineticsA Rozhkova *et al*

(Table II). The coordinates and structure factors of nDsbD-SS-cDsbD were deposited with the Protein Data Bank (<http://www.rcsb.org/pdb/>) with entry code 1SE1.

The stereochemistry of the nDsbD-SS-cDsbD structure was checked with WHAT_CHECK (Hooft *et al*, 1996) and PROCHECK (Laskowski *et al*, 1993). All figures were prepared with PyMOL (<http://www.pymol.org>; DeLano, 2002) except for Figure 1B, for which SwissPDB Viewer was used (<http://www.expasy.org/spdbv>; Guex and Peitsch, 1997). The interface areas of the nDsbD-SS-cDsbD and nDsbD-SS-DsbC complexes were calculated with the program Grasp (Nicholls *et al*, 1993). The shape complementarity of the interfaces of nDsbD-SS-cDsbD and nDsbD-SS-DsbC was calculated with the CCP4 program SC (Lawrence and Colman, 1993).

Summary

DsbD from *Escherichia coli* transports two electrons from cytoplasmic thioredoxin to the periplasmic substrate proteins DsbC, DsbG and CcmG. DsbD consists of an N-terminal periplasmic domain (nDsbD), a C-terminal periplasmic domain, and a central transmembrane domain. Each domain possesses two cysteines required for electron transport. Herein, we demonstrate fast ($3.9 \times 10^5 \text{ M}^{-1}\text{s}^{-1}$) and direct disulfide exchange between nDsbD and CcmG, a highly specific disulfide reductase essential for cytochrome *c* maturation. We determined the crystal structure of the disulfide-linked complex between nDsbD and the soluble part of CcmG at 1.94 Å resolution. In contrast to the other two known complexes of nDsbD with target proteins, the N-terminal segment of nDsbD contributes to specific recognition of CcmG. This and other features, like the possibility of using an additional interaction surface, constitute the structural basis for the adaptability of nDsbD to different protein substrates.

Introduction

Disulfide bond reduction in the oxidizing *Escherichia coli* periplasm is catalyzed by the inner membrane protein DsbD. DsbD transfers electrons originating from cytoplasmic NADPH via thioredoxin reductase and thioredoxin to the periplasm (Kadokura et al., 2003). DsbD consists of a central transmembrane domain (TMD), a periplasmic N-terminal immunoglobulin-like domain (nDsbD), and a C-terminal thioredoxin-like domain (cDsbD) (Gordon et al., 2000; Goulding et al., 2002; Kim et al., 2003). Each of the domains has one pair of cysteines that is essential for electron transport (Stewart et al., 1999). It is proposed that electrons are transferred across the inner *E. coli* membrane via intramolecular disulfide exchange between the three DsbD domains (Figure 1). First, electrons are transferred from thioredoxin to the TMD, followed by reduction of cDsbD

and finally of nDsbD (Collet et al., 2002; Goldstone et al., 2001; Katzen and Beckwith, 2003; Krupp et al., 2000; Rozhkova et al., 2004).

DsbC, DsbG and CcmG (DsbE) are known in vivo substrate proteins of DsbD. DsbC is a homodimeric, periplasmic disulfide isomerase that catalyzes rearrangement of incorrect disulfide bonds in scrambled polypeptides to the native conformation (Maskos et al., 2003; McCarthy et al., 2000; Missiakas et al., 1994; Zapun et al., 1995). DsbG is a homodimeric homolog of DsbC of unknown function (Andersen et al., 1997; Besette et al., 1999; van Straaten et al., 1998). CcmG is a membrane-anchored, highly specific disulfide reductase that is essential for *c*-type cytochrome maturation (Fabianek et al., 1998). Formation of mature cytochrome *c* requires ligation of heme to reduced thiols of a C-X-X-C-H motif of apocytochrome. Since DsbA, the periplasmic dithiol-oxidase, randomly introduces disulfide bonds in apocytochromes, bacteria have evolved a specialized redox system to revert these disulfides into reduced cysteine residues (Thony-Meyer, 1997). Besides DsbD and CcmG, CcmH is also involved in this system (Fabianek et al., 1999). Electrons are thought to be transferred from DsbD via CcmG and CcmH to apocytochrome *c* (Fabianek et al., 1999; Reid et al., 2001). The 1.14 Å crystal structure of a soluble fragment of CcmG from *Bradyrhizobium japonicum* revealed a thioredoxin fold with a characteristic groove near the C-X-X-C active site that has been proposed to interact either with DsbD and/or CcmH, and an unusual acidic environment at the active site (Edeling et al., 2004; Edeling et al., 2002).

We have recently solved the structure of the disulfide-linked complex between nDsbD and cDsbD (Rozhkova et al., 2004) that represents a trapped reaction intermediate in the intramolecular electron transfer cascade of DsbD, and we compared the structure with that of the complex between nDsbD and DsbC (Haebel et al., 2002). We also measured the kinetics of all disulfide exchange reactions for the disulfide bond formation and isomerization pathways. Here, we extend the kinetic analysis to the disulfide reduction pathway of cytochrome *c* maturation. We also present the structure of a disulfide-linked complex between nDsbD and the soluble fragment of CcmG from *E. coli*, which reveals the structural basis for the specific interaction between nDsbD and CcmG.

Results and Discussion

Rapid Disulfide Exchange Proves Direct Electron Flow from DsbD to CcmG

Two soluble leaderless CcmG constructs (CcmG_{Δ19–185} and CcmG_{Δ43–185}) were designed for crystallization purposes, expressed in the cytoplasm of *E. coli*, and purified. We determined the redox potentials of the active site disulfides by equilibration with DTT under standard conditions. The values of -0.203 V and -0.209 V obtained for CcmG_{Δ19–185} and CcmG_{Δ43–185} (Figure 2), respectively, are almost identical. The previously re-

Figure 1. Proposed Electron Flow Cascade from NADPH in the Cytoplasm to DsbC and CcmG in the Periplasm via Thioredoxin and DsbD

ported equilibrium constant between glutathione and CcmG_{Δ19-185} is 215 mM (Li et al., 2001). Our data are in good agreement with the corresponding CcmG_{Δ19-185} redox potential of -0.220 V, when calculated by using the standard redox potential of glutathione of -0.240 V (Williams, 1992).

Although the reduction of CcmG by nDsbD ($E_o' = -0.232$ V [Collet et al., 2002; Rozhkova et al., 2004]) would proceed just to $\sim 70\%$, overall electron transfer from thioredoxin ($E_o' = -0.270$ V [Krause et al., 1991]) via DsbD to CcmG is thermodynamically driven and guarantees effective reduction of CcmG.

The rate constants of the disulfide exchange between nDsbD and both CcmG constructs were determined by stopped flow fluorescence. Figures 3A and 3B show that reduction of CcmG_{Δ19-185} and CcmG_{Δ43-185} by nDsbD is very fast (3.0×10^5 M⁻¹s⁻¹ and 3.9×10^5 M⁻¹s⁻¹, respectively) and in the range of the known functional reactions between Dsb proteins in the periplasm with rate constants of $\sim 10^6$ M⁻¹s⁻¹ (Grauschopf et al., 2003; Rozhkova et al., 2004). The very similar rate constants indicate that residues A19–G42 of CcmG are not required for rapid electron transfer from nDsbD to CcmG. In addition, we showed that, as expected, no reaction between cDsbD and CcmG occurs (Figure 3C). Our kinetic data and the observation that DsbD and CcmG form a mixed disulfide in vivo (Katzen and Beckwith, 2000) support the existing model (Figure 1), according to which DsbD transfers electrons directly to CcmG (Fabianek et al., 1999; Reid et al., 2001) and not via CcmH, as proposed in an alternative model (Reid et al., 2001).

We also measured the kinetics of the direct oxidation of CcmG by DsbA. This reaction is kinetically restricted and extremely slow (0.31 M⁻¹s⁻¹), guaranteeing the resistance of the first reductive reaction step in the cytochrome c maturation pathway against oxidation in the

Figure 2. Determination of the Redox Potentials of CcmG_{Δ19-185} and CcmG_{Δ43-185}

A total of $2 \mu\text{M}$ CcmG_{Δ19-185} or CcmG_{Δ43-185} was incubated at 25°C and pH 7.0 in the presence of 50 mM DTT_{ox} and various concentrations of DTT_{red} (1.5 – 5 mM), and fluorescence at 335 nm was recorded. Data were normalized and fitted (solid line) according to Equation 1 (see Experimental Procedures). The calculated redox potentials of CcmG_{Δ19-185} and CcmG_{Δ43-185} are -0.203 V and -0.209 V, respectively.

periplasm (Figure 4). This, together with the observation that CcmG is more stable in the reduced state (Li et al., 2001), suggests that CcmG, when overexpressed in the periplasm, will accumulate at least partially in the reduced form, even in the absence of DsbD. This explains why mature cytochrome c could be detected in vivo when Ccm proteins were overexpressed in *dsbD* null mutants (Stevens et al., 2004).

Structure of the Mixed-Disulfide Complex

The structure of the mixed-disulfide complex of *E. coli* nDsbD and CcmG_{Δ43-185} (nDsbD-SS-CcmG, Figure S1; see the Supplemental Data available with this article online) was determined at 1.94 Å resolution. The final model of nDsbD-SS-CcmG (Figure 5A) encompasses residues R8–N125 of nDsbD and R49–A184 of *E. coli* CcmG (EC-CcmG) and exhibits very good geometry and stereochemistry (Table 1). Its Ramachandran plot contains two outliers (nDsbD Q26 and D79), both located in a β turn with well-defined electron density. D79 assumes the same conformation in all previously reported nDsbD structures (1L6P, 1JPE, 1JZD, 1SE1); Q26 is an outlier also in 1L6P and 1JPE. The side chain of residue R8 is rather disordered and was modeled in two alternative conformations.

In the nDsbD-SS-CcmG model, nDsbD has an average B-factor of 31.7 Å², much lower than that of EC-CcmG (51.0 Å²). This is probably due to the more limited participation of EC-CcmG in crystal contacts compared to nDsbD.

As already described, nDsbD possesses an immunoglobulin-like fold (Goulding et al., 2002). EC-CcmG possesses the same thioredoxin-like secondary structure motif found in *B. japonicum* CcmG (BJ-CcmG): $\beta_1\alpha_A\beta_2\alpha_B\beta_3\alpha_C\beta_4\beta_5\alpha_D$, preceded by an N-terminal extension that is seven residues shorter than in BJ-CcmG.

Figure 3. Kinetics of the Disulfide Exchange at pH 7.0 and 25°C between the Periplasmic Domains of DsbD and CcmG

(A and B) All reactions were performed in a stopped-flow fluorescence instrument under pseudo-first-order conditions, with initial protein concentrations of 10 μM for *nDsbD*_{red} or *cDsbD*_{red} and of 1 μM for *CcmG*_{Δ10-185} or *CcmG*_{Δ43-185}. The fit (solid line) yields rate constants of $3.0 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$ and $3.9 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$ for the reduction of (A) *CcmG*_{Δ10-185} and (B) *CcmG*_{Δ43-185}, respectively. Rate constants for the reverse reaction were calculated from the equilibrium constant ($K_{\text{eq}} = 6.0$) for the reduction of CcmG by *nDsbD*.

(C) No reduction of *CcmG*_{Δ43-185} by *cDsbD* is observed during 50 s after stopped-flow mixing.

This N-terminal extension shows a more similar overall conformation to that of CcmG from *Mycobacterium tuberculosis* (*MT-CcmG*) than to that of *BJ-CcmG*. Other differences reside in loop regions: the loop between

Figure 4. Oxidation of *CcmG*_{Δ43-185} by DsbA at pH 7.0 and 25°C is Very Slow

Measurements were performed under second-order conditions with initial protein concentrations of 50 μM . The fit (solid line) yields a rate constant of $0.31 \text{ M}^{-1} \text{ s}^{-1}$. The rate constant for the reverse reaction was calculated from the equilibrium constant ($K_{\text{eq}} = 750$) for the reduction of DsbA by *CcmG*_{Δ43-185}.

EC-CcmG α helix A and β strand 2 is one residue longer than in *BJ-CcmG*; the loop between β strands 4 and 5 in *EC-CcmG* (β strands 6 and 7 in *MT-CcmG*) takes up a different conformation in *MT-CcmG*. The loop between β strand 5 and α helix D in *EC-CcmG* (β strand 7 and α helix 6 in *MT-CcmG*) is two residues shorter than in *MT-CcmG*. Notably, in a hypothetical complex of *MT-CcmG* with *E. coli* *nDsbD*, this loop would cause steric clashes. This is presumably not the case in the complex of *MT-CcmG* with the proposed homolog of DsbD from *M. tuberculosis* (called *MT-DsbD* or DipZ, SwissProt: Q10801) (Juarez et al., 2001). The structure of *MT-DsbD* or its individual domains has not been determined yet (only a crystallization report of the C-terminal domain has been published [Goldstone et al., 2005]).

The *EC-CcmG* structure is very similar to that of *BJ-CcmG* ([Edeling et al., 2002], rmsd C α atoms 1.4 Å) and, to a lesser extent (rmsd 2.1 Å), to *CcmG* from the Gram-positive bacterium *M. tuberculosis* (Goulding et al., 2004) (Figure 5C). A DALI search (Holm and Sander, 1993) against the Protein Data Bank (www.pdb.org) identified two other periplasmic proteins from the thioredoxin superfamily that are structurally highly related to *EC-CcmG*: *Bacillus subtilis* ResA (rmsd 2.1 Å) (Crow et al., 2004), also involved in cytochrome *c* maturation, and *B. japonicum* TlpA (rmsd 2.4 Å) (Capitani et al., 2001), which is required for the stability and assembly of cytochrome *aa3*, a heme-copper terminal oxidase of the respiratory chain.

The crystal structure of *BJ-CcmG* revealed a characteristic groove near the active site that has been proposed to interact either with DsbD and/or CcmH (Edeling et al., 2004; Edeling et al., 2002). This groove is mainly formed by the already mentioned seven additional residues in the N-terminal extension of *BJ-CcmG*. *EC-CcmG* does not possess this characteristic groove. Superposition of *EC-CcmG* onto *BJ-CcmG* and analy-

(B) Close-up view of the *nDsbD-SS-CcmG* interface. *nDsbD* residues involved in the dimer interface are mapped in green onto the *nDsbD* surface. Interacting residues of *EC-CcmG* are shown in light gray and atom colors. Hydrogen bonds appear as yellow, dotted lines. R8 exhibits a double conformation.

(C) Superposition of the $C\alpha$ atoms of *BJ-CcmG* (marine) and *MT-CcmG* (violet) onto *EC-CcmG* (gray), in tube representation.

sis of the residues of *EC-CcmG* interacting with *nDsbD* show that the binding interface is not located near the groove region of *BJ-CcmG*.

nDsbD exhibits essentially the same binding orientation in the complexes with *CcmG* and with *cDsbD*. Also, the cap-loop region (D68–G72) of *nDsbD* (Goulding et al., 2002) assumes a similar conformation in the two complexes. On the other hand, based on the electron density and B factors, the cap-loop region is more flexible in *nDsbD-SS-CcmG*, with the side chain of F70 being not at all defined.

In addition to the active site disulfide bridge, the binding interface of *nDsbD-SS-CcmG* involves five intermolecular hydrogen bonds (Figure 5B, Table S1). *nDsbD* F11 undergoes a conformational change upon complex formation (Haebel et al., 2002). It is involved in hydrophobic interactions in all three structurally known complexes of *nDsbD*, but only in *nDsbD-SS-CcmG* does the main chain carbonyl of F11 form a hydrogen bond (Table S1) with *CcmG* Y141, a highly conserved residue (Figure S2). Also, *nDsbD* S9 hydrogen bonds *CcmG* Y141 and assumes a conformation that, among all known *nDsbD* structures, is similar only to that in complex B of *nDsbD-SS-cDsbD*, in which S9 is involved in a crystal contact. This additional feature suggests that *nDsbD* S9 and F11 contribute to the specific recognition of *EC-CcmG*. Alanine mutation studies (Edeling et al., 2004) showed that the acidic residues E86, E145, and D162 of *EC-CcmG* are required for efficient cytochrome *c* maturation. Our data demonstrate

that both E145 and D162, but not E86, contribute to the *nDsbD-SS-CcmG* binding interface. Part of the side chain of *CcmG* E145 (especially the $C\gamma$ methylene) forms a hydrophobic cluster with *nDsbD* F108, *CcmG* Y141, and *CcmG* A160 (Figure 6). The side chain carbonyl of *EC-CcmG* D162 interacts with the main chain carbonyl of *nDsbD* G107 through a bridging water molecule. *EC-CcmG* E86 contributes to the surface with its main chain, while its side chain is buried. Its carboxyl group is involved in a network of hydrogen bonds (*EC-CcmG* N74, *EC-CcmG* L163, and three bridging waters) stabilizing a region behind the interface with *nDsbD*. Similar long-range effects were already observed in other protein-protein interactions (de Vos et al., 1992). Overall, the decreased level of mature cytochrome *c* in *CcmG*_{E86A/E145A} and *CcmG*_{E86A/E145A/D162A} mutants can be explained by an impaired interaction of *CcmG* with *nDsbD*.

Helix α_B of *CcmG*, which is present in all *CcmG* homologs and in TlpA but not in thioredoxin, is essential for cytochrome *c* maturation (Edeling et al., 2002). This helix would be a candidate for specific substrate recognition by *CcmG*, but it hardly interacts with *nDsbD* in the *nDsbD-SS-CcmG* complex; it only makes two long-range contacts with flexible side chains (F70 and Y71) of the *nDsbD* cap-loop region, amounting to less than 1.0% of the interface area.

The binding interface area of the *nDsbD-SS-CcmG* complex (1432 Å² and 1322 Å², respectively, depending on which conformation of R8 is chosen) is similar to

that in nDsbD-SS-cDsbD (1301 Å²) and in nDsbD-SS-DsbC (1376 Å², primary interface only) (Rozhkova et al., 2004). nDsbD-SS-CcmG has a surface complementarity index of 0.82 (Table 2), which is higher than those of nDsbD-SS-cDsbD and nDsbD-SS-DsbC (Rozhkova et al., 2004). Figure 7 shows surface (top) and full-atom representations (bottom) of nDsbD in the complexes with EC-CcmG ([A] and [B]), DsbC ([C] and [D]), and cDsbD ([E] and [F]). Notably, the majority of the nDsbD residues involved in the binding with thioredoxin-like partner interfaces are common (depicted in green in Figure 7). Only a few residues form contacts that are specific to one nDsbD-substrate complex (depicted in

blue). As already mentioned, two flexible regions of nDsbD are involved in the recognition of thioredoxin-like substrates: the cap-loop region and the N-terminal segment. The latter one especially exhibits a great adaptability, as can be seen from the position of R8 and S9 in nDsbD-SS-CcmG (Figures 7A and 7B) and in nDsbD-SS-DsbC (Figures 7C and 7D): the violet area indicating R8 is found in two very different positions in the two cases, and, for nDsbD-SS-DsbC, this residue is partly disordered (Haebel et al. [2002] only modeled it to Cβ). In fact, in nDsbD-SS-cDsbD, the N-terminal segment (S9 and F11) participates only to a modest amount and without hydrogen bonding to the binding interface (for this comparison, one has to use complex C of nDsbD-SS-cDsbD, which, in contrast to the other two in the asymmetric unit, is not influenced by crystal contacts in the N-terminal region [Rozhkova et al., 2004]). In nDsbD-SS-DsbC, the N-terminal segment also has a very modest interaction with the binding partner DsbC; S9 and F11 participate marginally to the interface. As mentioned above, in this case R8 is partly disordered and also has very high B factors.

While nDsbD is connected by a 20 residue long linker to the transmembrane domain of DsbD, EC-CcmG is connected by a linker of similar size (23 residues if one considers CcmG_{Δ43–185}, for which the first well-defined residue is R49) to a single transmembrane helix (Figure 1). We previously proposed (Rozhkova et al., 2004) a likely orientation of nDsbD-SS-cDsbD relative to the membrane and pointed out that a large rotational motion of the nDsbD domain must occur for the interaction with DsbC. The nDsbD-SS-CcmG structure allows us to expand this model. The N termini of EC-CcmG, BJ-CcmG, *B. subtilis* ResA, and *B. japonicum* TlpA all point in the same direction, most likely toward the membrane: in fact, in the nDsbD-SS-CcmG complex, the N-terminal segment of the folded thioredoxin domain of CcmG is located close to a large relatively planar region, likely parallel to the membrane (Figure S3). According to this model, nDsbD must undergo a large displacement from its position in nDsbD-SS-cDsbD in order to access the active site disulfide of EC-CcmG (Figure 8). This mobility of nDsbD is essential for disulfide exchange between nDsbD and its substrates.

We demonstrate an intriguing ability of the N-terminal domain of DsbD to interact specifically and very rapidly with different target proteins such as the periplasmic dimer DsbC and the membrane-anchored monomer CcmG. The structural basis for this feature is at least 2-fold: first, nDsbD possesses two different interaction surfaces, one of which is only used for the reaction with

Figure 6. Detail of the Complex Interface around Y141 of CcmG

CcmG Y141 and A160 appear in cobalt and atom colors, the two acidic residues E145 and D162 in yellow and atom colors, and other residues in gray. F108 of nDsbD is depicted in violet; other nDsbD residues are depicted in red.

a dimeric partner, DsbC. In the nDsbD-SS-CcmG complex, the N-terminal segment of nDsbD also contributes to the recognition of CcmG (Figure 6, Figure S4). In addition, the main interaction surface around the active site disulfide of nDsbD, which is used in all three structures of nDsbD complexes (Figure S4), combines a comparatively small area with excellent adaptability to various thioredoxin-like partner interfaces (Figure 7). These unusual properties of nDsbD enable the inner membrane redox catalyst DsbD to provide two different systems, the disulfide bond isomerization and cytochrome *c* maturation pathways, with reducing equivalents.

Experimental Procedures

Construction of Expression Plasmids

For cytosolic expression of CcmG_{Δ10-185} (residues 19–185) and CcmG_{Δ43-185} (residues 43–185) with C-terminal (His)₆ tag, two plasmids were constructed: pCcmG_{Δ10-185} and pCcmG_{Δ43-185}, respectively. The corresponding 519 bp or 447 bp gene fragment was amplified by PCR from the plasmid pEC86 (Arslan et al., 1998) encoding the *E. coli* *ccm* gene region with primers E1a (5'-CCCAAT

CCATATGGGCTGTGTGGCAGC-3') or E1b (5'-CCCAATCCATATGAAGCCTGTGCGAAGTTTCG-3') and E2 (5'-CGCGGATCCTTATGGTGATGGTGATGGTGTGTGGCGGCCTCCTACT-3') and was cloned into pET11a via NdeI and BamHI (Novagen).

The Cys variants of CcmG_{Δ10-185} and CcmG_{Δ43-185}, in which the second active site cysteine was replaced by serine, were constructed from pCcmG_{Δ10-185} and pCcmG_{Δ43-185} by using Quik-Change (Stratagene). All constructs were verified by DNA sequencing.

Purification of CcmG_{Δ10-185}, CcmG_{Δ43-185}, nDsbD, cDsbD and DsbA (His)₆-tagged CcmG_{Δ10-185} and CcmG_{Δ43-185} were expressed in *E. coli* BL21Tuner (DE3) cells (Novagen) grown in Luria-Bertani (LB) medium containing ampicillin (100 μg/ml) at 37°C. Protein production was induced with IPTG to a final concentration of 100 μM when cells reached an O.D. of 0.7–0.8 at 600 nm. After further growth at 37°C for 3 hr, bacteria were harvested by centrifugation. Cells were suspended in ice-cold PBS buffer (20 mM sodium phosphate [pH 7.5], 150 mM NaCl) and disrupted with a Cell Cracker (Avestin). After centrifugation at 45,000 × g for 30 min at 4°C, the supernatant was mixed with imidazole-HCl (pH 7.5) to a concentration of 10 mM and was applied to a Ni-NTA SuperFlow column (Qiagen) equilibrated with PBS containing 10 mM imidazole-HCl (pH 7.5). Proteins were eluted with a gradient of imidazole-HCl from 10 mM to 200 mM. Fractions containing CcmG were pooled, mixed

Figure 7. Dimer Interface Comparison in the Three Known Complexes of nDsbD

(A–F) Surface (top) and ball-and-stick representations (bottom) of nDsbD in ([A] and [B], respectively) nDsbD-SS-CcmG, ([C] and [D], respectively) nDsbD-SS-DsbC (1JZD), and ([E] and [F], respectively) nDsbD-SS-cDsbD (1SE1 chain C). nDsbD residues involved in the interaction with the partner in all three complexes are depicted in green; residues involved in interactions specific to one complex are depicted in blue. R8 is shown in violet (in nDsbD-SS-CcmG, only one conformation is chosen; R8 in 1JZD is only partially defined, up to Cβ; R8 is not defined at all in 1SE1 chain C).

Crystal Structure of nDsbD-SS-CcmG

Figure 6. A Model for Domain Movement in Reductive Electron Transfer Mediated by DsbD

Left: proposed relative orientation of nDsbD-SS-CcmG to the membrane. Right: relative orientation of the nDsbD-SS-cDsbD model to the transmembrane domain full-length DsbD. EC-CcmG C80, nDsbD C109, and cDsbD C461 are depicted as yellow spheres; TMD C163 and C285 are indicated by yellow circles. Residues predicted to form flexible linkers are depicted as black lines.

with oxidized DTT (final concentration 50 mM), and incubated at room temperature for 30 min. After concentration, the protein pool was applied to a gel filtration column Superdex 75 16/60, equilibrated with 50 mM sodium phosphate, 300 mM NaCl (pH 7.0). Fractions containing pure CcmG were dialyzed against distilled water. Both CcmG constructs were fully oxidized after purification, as confirmed by Ellman's assay (Ellman, 1959) under denaturing conditions. The final yields of purified CcmG_{Δ10-185} and CcmG_{Δ43-185} were 100 and 120 mg/L bacterial culture, respectively.

The (His)₆-tagged variant C83S of CcmG_{Δ43-185} was expressed and purified according to the same protocol with comparable yields. nDsbD wild-type and its C103S variant, (His)₆-tagged cDsbD, and DsbA were expressed and purified as described (Rozhkova et al., 2004; Wunderlich and Glockshuber, 1993).

Synthesis of the nDsbD-SS-CcmG Complex

First, we prepared the mixed disulfide between nDsbD variant C103S and nitrothiobenzoic acid as described (Rozhkova et al., 2004). The purified, NTB-modified nDsbD variant C103S and the (His)₆-tagged variant C83S of CcmG_{Δ43-185} were dialyzed separately against PBS (pH 7.5), were then mixed at equimolar concentrations (50 μM each), incubated at 25°C for 30 min, and applied to a Ni-NTA SuperFlow column (Qiagen), equilibrated with PBS (pH 7.5). Proteins were eluted with a gradient of imidazole-HCl from 0 to 150 mM. Fractions containing the mixed-disulfide complex were pooled, concentrated, and applied to a gel filtration column Superdex 75 16/60, equilibrated with 50 mM sodium phosphate, 300 mM NaCl (pH 7.0). Fractions containing pure nDsbD-SS-CcmG complex (Figure S1) were dialyzed against 20 mM HEPES-NaOH, 50 mM NaCl (pH 7.0) and were concentrated.

Protein Concentrations

Protein concentrations of CcmG_{Δ10-185} and CcmG_{Δ43-185} were determined by using the extinction coefficients at 280 nm of 43,100 M⁻¹s⁻¹ and 37,530 M⁻¹s⁻¹, respectively. For nDsbD, cDsbD, and DsbC, the same extinction coefficients at 280 nm as in previous work were used (Rozhkova et al., 2004).

Redox Potential Determination

For determination of equilibrium constants (K_{eq}) between CcmG_{Δ10-185} or CcmG_{Δ43-185} and DTT, the redox state of the proteins at different DTT_{red}/DTT_{ox} ratios was determined by the change in the fluorescence at 335 nm. Proteins (2 μM) were incubated for 15 hr at 25°C in 100 mM sodium phosphate, 0.1 mM EDTA (pH 7.0) containing 50 mM DTT_{ox} and different amounts of DTT_{red} (1.5–5 mM). To exclude air oxidation, all buffers were degassed and flushed with argon. Data were fitted according to:

$$R = ([\text{DTT}_{\text{red}}] / [\text{DTT}_{\text{ox}}]) / (K_{eq} + [\text{DTT}_{\text{red}}] / [\text{DTT}_{\text{ox}}]), \quad (1)$$

where R is the fraction of reduced CcmG at equilibrium. Standard redox potentials (E'_0) were calculated by the Nernst equation:

$$E'_{\text{protein}} = E'_{\text{reference}} - (RT/2F)\ln K_{eq}, \quad (2)$$

by using a value of -0.307 V for the redox potential of DTT_{red}/DTT_{ox} (Rothwarf and Scheraga, 1992).

Stopped-Flow Experiments

The kinetics of the reduction of CcmG_{Δ10-185} and CcmG_{Δ43-185} by nDsbD in 100 mM sodium phosphate, 0.1 mM EDTA (pH 7.0) were monitored at 25°C by the change in fluorescence at 335 nm by using stopped-flow mixing in an Applied Photophysics SX-17MV instrument (1:1 volume mixing ratio). Measurements were performed under pseudo-first-order conditions with initial protein concentrations of 1 μM for the oxidized CcmG constructs and 10 μM for reduced nDsbD. Reduced nDsbD was prepared by reduction with a 1000-fold molar excess of DTT at pH 8.0, followed by removal of DTT by gel filtration in degassed buffer. Data from ten independent measurements were averaged and evaluated according to pseudo-first-order kinetics.

HPLC Analysis of Disulfide Exchange between DsbA and CcmG

To determine the second-order rate constants of the reduction of DsbA by CcmG_{Δ10-185} or CcmG_{Δ43-185}, proteins were mixed at equimolar concentrations (50 μM of each) and incubated at 25°C in 100 mM sodium phosphate, 0.1 mM EDTA (pH 7.0). Samples were removed at different incubation times, and the reaction was stopped by the addition of formic acid to a final concentration of 10% (v/v). Reaction products were separated on an Agilent Zorbax 300 SB C₁₈ reverse-phase column (5 mM, 2.1 × 150 mm) at 55°C with a linear gradient from 39% to 44% (v/v) of acetonitrile in 0.1% TFA and were detected by their absorbance at 220 nm and 280 nm. The amounts of the reduced and oxidized forms of DsbA were quantified by integration of the peak areas. The data were evaluated according to second-order kinetics.

Crystallization

Purified, disulfide-linked nDsbD-SS-CcmG complex in 20 mM HEPES-NaOH [pH 7.0] and 50 mM NaCl was concentrated to 70 mg/ml. Crystals were produced by using the sitting drop vapor diffusion method. Protein solution (2.25 μl) was mixed with 1.5 μl precipitant solution (0.1 M sodium acetate [pH 4.5], 0.2 M MgCl₂, 15% PEG 4000). nDsbD-SS-CcmG crystals grew within 3 days at 4°C.

Data Collection and Structure Solution

Crystals were cryoprotected by adding 22.5% ethylene glycol to the mother liquid and were directly frozen in a nitrogen gas stream. Using a MAR CCD 165 image plate, diffraction data were measured on beamline X06SA at the Swiss Light Source (Paul Scherrer Institut Villigen, Switzerland) at a wavelength of 0.9004 Å with an aluminum filter ($l = 0.79$ l₀). Data were processed with DENZO and SCA-LEPACK (Otwinowski and Minor, 1997) to a resolution of

Structure
992

1.94 Å. nDsbD-SS-CcmG crystals belong to the monoclinic space group P2₁, with a = 53.57 Å, b = 53.17 Å, c = 63.83 Å, β = 104.88°, and contain one complex per asymmetric unit.

The structure was solved by molecular replacement with Phaser-1.2 (Storoni et al., 2004). Model rebuilding was carried out with the program O (Jones and Kjeldgaard, 1991), and the model was finally refined with CNS to an R-factor of 0.235 and an R_{free} of 0.271. The geometry and stereochemistry of the nDsbD-SS-CcmG structure were checked with WHAT_CHECK (Hoofst et al., 1996) and PROCHECK (Laskowski et al., 1993). The interface area of the nDsbD-SS-CcmG complex was calculated with the program GRASP (Nicholls et al., 1993) by following the method published by Janin (1997). The surface complementarity of the interfaces of nDsbD-SS-CcmG was calculated by using the CCP4 program SC (Lawrence and Colman, 1993). All structural figures were prepared with PyMOLv0.97 (<http://www.pymol.org>).

Supplemental Data

Supplemental Data including a hydrogen bonding table and three additional figures are available at <http://www.structure.org/cgi/content/full/13/7/985/DC1/>.

Acknowledgments

This project was funded by the Schweizerische Nationalfonds, the Eidgenössische Technische Hochschule Zurich, and the University of Zurich in the framework of the National Center of Competence in Research Structural Biology program. X-ray data collection was performed at the Swiss Light Source. We thank L. Thöny-Meyer (for kindly providing us with plasmid pEC86 and for reading the paper), R. Brunisholz, and H. Rechsteiner.

3.3 High resolution structural studies of oxidized, reduced and photo-reduced *Escherichia coli* cDsbD (paper in preparation)

Christian U. Stirnimann[†], Anna Rozhkova[†], Ulla Grauschopf, Markus G. Grütter, Rudi Glockshuber, and Guido Capitani

Running title: Structural studies of cDsbD

[†]These authors contributed equally to this work

Introduction

Dsb proteins catalyze oxidative protein folding in the periplasm of *Escherichia coli*. Formation of native disulfide bonds involves two independent pathways: the oxidative DsbA/B pathway and the reductive DsbC/D pathway.^{1; 2} The strong dithiol oxidase DsbA very rapidly and randomly introduces disulfide bonds into reduced polypeptides.^{3; 4; 5} Upon oxidation of substrate proteins DsbA becomes reduced and is re-oxidized by the inner membrane protein DsbB, that transfers electrons from DsbA to ubiquinone.^{6; 7; 8; 9} Since DsbA has no “proofreading” activity, rearrangement of wrong disulfide bonds in scrambled polypeptides to the native disulfide pattern is catalyzed by the periplasmic disulfide isomerase DsbC.^{10; 11; 12; 13} The inner membrane protein DsbD is required for maintenance of DsbC in its active, reduced state in the highly oxidizing periplasm. DsbD also supplies two other periplasmic proteins with reducing power: DsbG, a homologue of DsbC of unknown function^{14; 15; 16}, and CcmG, a specialized thiol reductase, essential for cytochrome *c* maturation.¹⁷

DsbD consists of three domains: a N-terminal periplasmic domain (nDsbD) with an immunoglobulin fold,^{18; 19} a central transmembrane domain (TMD), composed of eight predicted transmembrane helices,²⁰ and a C-terminal periplasmic thioredoxin-like domain (cDsbD).²¹ Each domain has two conserved cysteine residues, essential for electron transport.²² It is proposed that intramolecular electron transfer within DsbD proceeds exclusively through sequential disulfide exchange reactions between its three domains.^{23; 24; 25;}²⁶ The electron cascade starts with the reduction of TMD by thioredoxin, then cDsbD shuttles electrons from TMD to nDsbD, and finally reduced nDsbD passes electrons to DsbC, DsbG or CcmG.

The 1.9 Å crystal structure of oxidized cDsbD (residues 423–546 of mature *Escherichia coli* DsbD) revealed a thioredoxin fold with an extended N-terminal stretch.²¹ We have recently determined the structure of a disulfide-linked complex between cDsbD and nDsbD (2.85 Å resolution), which represents an important reaction intermediate in the catalytic cycle of DsbD.²⁷

For better understanding of the redox mechanism of cDsbD, we determined four high-resolution structures of cDsbD: chemically reduced (1.3 Å), pH-shifted chemically reduced (0.99 Å), photo-reduced (1.1 Å), and oxidized (1.65 Å) cDsbD. The structure of reduced cDsbD revealed that the active site Cys461 is protonated at pH 7.0. In order to determine the *pKa* value of Cys461, we studied the pH-dependent reactivity of Cys461 with the alkylating reagent iodoacetamide and also the pH-dependent thiolate-specific absorbance at 240 nm.

These experiments showed that cDsbD active site Cys461 has an unexpectedly high pK_a value of 9.3 for a thioredoxin-like protein with a redox potential of -235 mV.^{27; 28; 29}

RESULTS AND DISCUSSION

Thermodynamic stabilities of the redox forms of cDsbD

Guanidinium chloride (GdmCl) induced unfolding and refolding transitions of the oxidized and reduced cDsbD at 25°C and pH 7.0 were followed by fluorescence at 345 nm (excitation at 280 nm). The transitions were cooperative and fully reversible (Fig. 1A). Evaluation of the data according to the two-state model yielded ΔG -values of $-43.9(\pm 2.9)$ kJ mol⁻¹ for cDsbD_{ox} and $-45.5(\pm 5.0)$ kJ mol⁻¹ for cDsbD_{red}, indicating that at pH 7.0 both redox forms are equally stable.

p*K*_a of the active site Cys461 and reactivity with DTT

To determine the p*K*_a of the nucleophilic active-site Cys461, we first investigated the pH-dependent reactivity of Cys461 with iodoacetamide (IAM).^{6; 7; 8; 9} cDsbD_{red} (5 μM) was mixed with an excess of IAM (between 0.1 mM and 10 mM) in the range of pH 4-10. Samples were removed after different incubation times, and the reaction was quenched with acid. The reaction products were separated by reversed-phase HPLC, and amounts of reduced and IAM-modified cDsbD were quantified by integration of the peak areas. Figure 1B shows the pH-dependence of the apparent second-order rate constant (*k*_{IAM}) of the alkylation of Cys461 in reduced cDsbD by IAM. The transition appeared to be biphasic as it had previously been described for thioredoxin.^{6; 7; 8; 9} Although this method did not provide an exact p*K*_a value, we can conclude that the p*K*_a of Cys461 is above 8.0. We then investigated the pH-dependence of the thiolate-specific absorbance at 240 nm.^{30; 31; 32} The protein solution (initial concentration of 30 μM) was titrated in the range of pH 4-12 and the absorbance at 240 nm and 280 nm was recorded. Far-UV CD measurements proved that the secondary structure of cDsbD is not changed in this pH-range (data not shown). The titration curves of cDsbD_{red} (circles) and its single cysteine variant cDsbD-Cys464Ser (squares) are depicted in Figure 1C. Both cDsbD_{red} and cDsbD-Cys464Ser showed a single transition with a midpoint at pH 9.2-9.5. From these data we can conclude that Cys461 has an unusually high p*K*_a of about 9.3 that is similar to the p*K*_a of a normal cysteine thiol. It has been shown that the p*K*_a of the nucleophilic active site thiols in DsbA and thioredoxin variants is lowered and correlates with the redox potential of these enzyme.^{30; 31; 32} cDsbD has a redox potential of -235 mV.^{27; 28} Accordingly, the corresponding theoretical p*K*_a of Cys461 lies between 6 and 7. Although the determined p*K*_a of cDsbD Cys461 deviates significantly from theory, it is consistent with our results obtained by the IAM-modification method (Fig. 1B) and the identical stabilities of both redox forms.

We also studied the reactivity of cDsbD_{ox} with DTT at 25°C and pH 7.0. Measurements were carried out under pseudo-first order conditions with initial concentrations of cDsbD_{ox} and DTT of 5 μM and 1 mM, respectively. Samples were removed at different incubation times, and the reaction was quenched with acid. Reaction products were separated by reverse-phase HPLC, and amounts of cDsbD_{ox} and cDsbD_{red} were quantified by integration of the peak areas. Figure 1C shows that the reduction of cDsbD_{ox} by DTT is in contrast to electron transfer between other Dsb proteins very slow, with an apparent second order rate constant (15 M⁻¹ s⁻¹) typical for the thiol-disulfide exchange between small organic molecules.³³

Crystallization of cDsbD

Oxidized and chemically reduced cDsbD (termed cDsbD_{ox} and cDsbD_{red} from now on) crystallized under the same conditions. The first dataset collected for cDsbD_{ox} turned out to be photoreduced (termed cDsbD_{pr} from now on). A dataset of cDsbD in an intact oxidized state (cDsbD_{ox}) was measured from a crystal grown under similar conditions (see experimental part). In both cases the crystals grew within 3 to 5 days. cDsbD formed plate-like crystals with dimensions of about 100 x 650 x 30 μm which were arranged in bundles and star-like structures. Before being removed from the drop the crystal bundles were separated into single-crystal fragments. All crystals belong to the orthorhombic space group P2₁2₁2₁ with similar cell parameters and contain one molecule per asymmetric unit. In comparison, the lower-resolution SeMet cDsbD crystals reported by Kim *et al.* (2003)²¹ exhibited the same unit cell (resolution 2.3 Å) and the native crystals contained two molecules per asymmetric unit (resolution 1.9 Å).

X-ray structure determination of cDsbD and structural quality

The X-ray structure of cDsbD_{ox} was first solved by molecular replacement using data from a crystal that diffracted to 1.1 Å and turned out to be photoreduced by synchrotron radiation (cDsbD_{pr}). The crystal packing is extremely dense with a very low Matthews-parameter of 1.7 Å³Da⁻¹.

cDsbD_{pr} was refined anisotropically to a resolution of 1.1 Å (Table 1). Given the high resolution of the data, hydrogen atoms could be included into the final stage of refinement. The final R factor is 0.148 and the free R-factor 0.174.

To protect the catalytic disulfide bridge of cDsbD_{ox} from radiation damage, a second dataset was measured using an aluminium filter that decreased the beam intensity to 70.3 % of the original value. A shorter wavelength (0.751 Å) was chosen to reduce radiation damage to the

disulfide bridge.³⁴ The crystal diffracted to 1.65 Å and the disulfide bridge was found to be intact: no positive or negative difference density is visible at this site (Table 1). cDsbD_{red} data were collected at a wavelength of 1.000 Å to a resolution of 1.3 Å.

The fourth dataset (termed cDsbD_{red/pH7} from now on) was collected from a chemically reduced crystal with a shift to pH 7 at a wavelength of 0.86 Å to a resolution of 0.99 Å using the same aluminium filter as described for cDsbD_{ox}. cDsbD_{red/pH7} was anisotropically refined to a resolution of 0.99 Å. Since mostly all main-chain and several side-chain hydrogen atoms were already visible after the fourth refinement cycle they were included into the refinement. All four final atomic models exhibit excellent Ramachandran plot statistics with all residues found in most favoured and additionally allowed regions (Table 1).

Overall structure and comparison of different cDsbD structures

cDsbD possesses a thioredoxin-like fold as already described. In the following we use the nomenclature introduced by Kim *et al.* (2003).²¹

The structure of cDsbD is very rigid. Except for the active-site region, systematic superposition of cDsbD_{ox}, cDsbD_{pr}, cDsbD_{red} and cDsbD_{red/pH7} reveals no significant structural change. Rmsd-values for all pairs of structures lie in the 0.17 - 0.36 Å range. The sulfur of Cys464 moves by 0.5 Å towards the interior of the protein upon reduction (comparing cDsbD_{ox} and cDsbD_{red}). This corresponds to a change by 11° in the χ_1 angle of Cys464. For the accessible Cys461, the ϕ angle changes by 7° and the χ_1 angle by 9°. The S-S distance in cDsbD_{red} is 3.6 Å.

Upon superposition of the cDsbD domain from the nDsbD-SS-cDsbD complex (termed cDsbD_{co} from now on)²⁷ onto unliganded cDsbD, only helix α_2a (including the two active site cysteines) and Thr529 exhibit differences. In the complex, helix α_2a is slightly pulled towards the Cap-loop region of nDsbD (Asp68-Gly72)¹⁸ probably as a consequence of the Cys461 (cDsbD) - Cys109 (nDsbD) disulfide bond formation. The main chain carbonyl of Thr529 is forced by direct van der Waals interactions of the two side chains of Phe11 and Phe108 of nDsbD to take up a different conformation with respect to unbound cDsbD: ϕ and ϕ change by approximately 10° and 100°, respectively (Figure 2).

In general, compared to nDsbD that undergoes a huge opening of the Cap-loop region upon complex formation,²⁷ cDsbD exhibits only small structural rearrangements.

Radiation driven disulfide-reduction of cDsbD_{pr}

The most radiation-sensitive moieties in proteins are disulfide bonds.^{35; 36; 37} The first step of the radiation-driven opening of a disulfide bond is the trapping of an electron (RSSR[•]). Spontaneous and reversible bond rupture to RS[•] and RS⁻ can then occur. The protonation of this radical (RSSRH[•]) shifts the equilibrium towards the broken state upon bond rupture to a thiol (RSH) and a thiyl radical (RS[•]). Figure 3 shows an overview of the disulfide opening mechanism.^{38; 39; 40; 41}

Analysis of the cDsbD_{pr} data set shows that opening of the Cys461-Cys464 disulfide bridge occurs during data collection. We analysed this phenomenon by partitioning the dataset into eight incremental reflection files. In the first reflection file 150 diffraction images were included. For every additional reflection file, the number of diffraction frames included was increased by 50. An independent refinement with CNS⁴² at 1.4 Å resolution was then carried out for each dataset. In all cases, van der Waals interactions between the two sulfur atoms of the active site cysteines were made to be ignored during refinement in CNS. The refined S-S distances were found to increase at each step: from 2.44 Å for the first 150-frames reflection file to 2.65 Å for that containing 500 data-frames. Already for the first reflection file, opening of the disulfide bridge is clearly visible. The observed disulfide distance is 0.39 Å higher than that observed for cDsbD_{ox} (2.05 Å). To analyse the state of the disulfide bridge at the end of the measurement two additional reflection files were created, encompassing frames 349 to 559 (refined S-S distance of 2.96 Å) and of frames 420 to 676 (refined S-S distance of 2.99 Å). These values clearly indicate that even after full crystal exposure the disulfide bridge is not fully reduced (for comparison: cDsbD_{red} shows a distance of 3.56 Å). The analysis is summarized in Table 2.

Comparison with cDsbD in other prokaryotic organisms

18 entries for DsbD were found in a SwissProt database⁴³ search (www.expasy.org/sprot/). A multiple sequence alignment of the cDsbD domains from those sequences was carried out. Identical sequences were ignored for the alignment. The cDsbD sequence of *Salmonella typhi*, differing from that of *Salmonella typhimurium* by only four residues, all found in highly variable regions, was also ignored. As shown in Figure 4A, *E. coli* has the shortest cDsbD-sequence. Highly conserved regions (Figure 4A) are visible in the multiple sequence alignment. Except for *Campylobacter jejuni* cDsbD, the active site motif is YADWC(V,I)(A,S)CK. *C. jejuni* exhibits the active site pattern: TASWCENCK. This is consistent with the fact that cDsbD of *C. jejuni* has the lowest sequence identity and the

second last similarity of all sequences used. The more distant relationship of *C. jejuni* cDsbD to the rest of the group is also indicated by phylogenetic analysis of the DsbD family and their homologs by Kimbal *et al.*⁴⁴ Their tree was built using multiple sequence alignments of the DsbD transmembrane helices 1 to 6 using homolog sequences from all Gram-negative (G-) protobacteria, G-bacteria, Gram positive (G+) bacteria, Archaea, Thermatoga and Cyanobacteria. According to the different branches of the tree, the authors defined the different Dsb-family sequences in 17 clusters. G- proteobacteria Dsb-family proteins and homologs resulted in 5 clusters whereas cluster 1 consists of G- proteobacterial DsbDs. Cluster contains two main branches. The first branch contains the DsbD protein from *N. meningitidis* and *C. jejuni* whereas the main branch consists of all the others (Kimbal *et al.* did not include *Vibrio parahaemolyticus*, *Vibrio vulnificus*, *Salmonella typhimurium* and *Ralstonia solanacearum* in the analysis).

The conserved residues were mapped onto the cDsbD structure. Figure 4B indicates that most residues located in the binding interface of cDsbD to nDsbD are highly conserved. Not surprisingly, hardly any conserved residue can be found on the opposite site of the cDsbD surface (Figure 4C).

MATERIALS AND METHODS

Protein purification

(His)₆-tagged cDsbD and its single cysteine variant cDsbD-Cys464Ser (a.a numbering corresponds to the mature full length DsbD) were overexpressed in *E. coli*, purified, and protein concentration was determined as described.²⁷

Stability measurements

GdmCl-induced unfolding and refolding of oxidized and reduced forms of cDsbD were performed at 25°C in 20 mM HEPES, 170 mM NaCl, 0.1 mM EDTA (pH 7.0). In the case of reduced cDsbD, 0.5 mM DTT was included. For unfolding, 2.5 μM protein was incubated for 15 h with various concentrations of GdmCl. For refolding, 125 μM protein was first denatured with 6 M GdmCl for 3 h at 25°C, then diluted 1:50 into refolding buffer with various concentrations of GdmCl and incubated for 15 h. The transitions were followed by the fluorescence at 345 nm (excitation at 280 nm). Data were evaluated according to the two-state model with a six-parameter fit.⁴⁵

HPLC measurements

HPLC analysis was performed on an Agilent 1100 HPLC instrument equipped with a diode array detection system and an Agilent Zorbax 300 SB C₁₈ reversed-phase column (5 mM, 2.1 x 150 mm). Different species of cDsbD were separated at 55°C with a linear gradient from 35 % to 55 % (v/v) of acetonitrile in 0.1 % TFA, and detected by their absorbance at 220 nm and 280 nm. The amounts of reduced, oxidized or IAM-modified forms of cDsbD were quantified by integration of the peak areas.

Determination of the pK_a of the active site Cys461

All experiments were performed at 25°C in the reaction buffer (200 mM KCL, 10 mM disodium hydrogen phosphate, 10 mM boric acid, 10 mM succinic acid, 0.1 mM EDTA), adjusted with HCl or NaOH to pH 4–12. Reduced cDsbD was prepared by reduction with a 1000-fold molar excess of DTT at pH 8.0 for 30 min at room temperature, followed by removal of DTT by gel filtration in degassed buffer.

The ionization of Cys461 was measured by the pH-dependent reactivity with iodoacetamide (IAM).^{30; 46} Reactions were performed under pseudo-first order conditions with initial cDsbD_{red} concentration of 5 μM, and IAM concentrations between 0.1 mM and 10 mM. Samples were removed after different incubation times. The reaction was stopped by addition of 0.4 volumes of 30 % (v/v) formic acid (final pH < 2), and HPLC analysis were performed as described. Data were evaluated according to pseudo-first order kinetics. The apparent second-order rate constants (k_{IAM}) were calculated and plotted against pH.

The pK_a of Cys461 in cDsbD or cDsbD-Cys464 was alternatively measured by the pH-dependent thiolate-specific absorbance at 240 nm.^{30; 31; 32} Initial protein concentration was 30 μM. The sample absorbance was measured against air and was corrected for the dilution caused by pH adjustment and for the absorbance of a protein-free reference solution, titrated in the same manner. The data was evaluated according to the Henderson-Hasselbach equation as described previously.³¹

HPLC analysis of the reactivity with DTT

Measurements were performed under pseudo-first order conditions with an initial concentration of oxidized cDsbD of 5 μM and 1 mM of DTT at 25°C in 100 mM sodium phosphate, 0.1 mM EDTA (pH 7.0). Samples were removed after different incubation times, and reaction was stopped by addition of 0.4 volumes of 30 % (v/v) formic acid (final pH < 2).

HPLC analyses were performed as described. Data were evaluated according to pseudo-first order kinetics and the apparent second order rate constants were calculated.

Crystallization of cDsbD

Purified cDsbD was concentrated to 19.3 mg/ml. The sitting drop vapour diffusion method was used for producing crystals. In the case of cDsbD_{pr} and cDsbD_{red} 1.4 μ l of protein solution were mixed with 2 μ l of precipitant solution (0.1 M ammonium acetate, 0.2 sodium acetate pH 4.6, 0.1 M sodium iodide, 40 % PEG 4K and for cDsbD_{red} additionally 0.3 mM TCEP HCl). The crystals used for cDsbD_{pH7} grew under the same condition as that the one used for cDsbD_{pr} and cDsbD_{red}, but the drop size was 2 μ l (1 μ l in protein + 1 μ l precipitant solution) each. The second cDsbD_{ox}-crystal measured was crystallized in 0.3 M sodium acetate pH 4.6, 0.1 M sodium iodide and 40 % PEG 4K whereas 0.8 μ l of protein solution were mixed with 2 μ l of precipitant solution. In both cases plate-like crystals grew at 4 °C within three to five days to maximum dimensions for a single crystal of 130 x 500 x 30 μ m. Reduced cDsbD was obtained by adding 3 mM Tris(2-carboxyethyl)phosphine (TCEP HCl) to oxidized cDsbD. Crystals grew under the same conditions as described for the oxidized form.

Data collection and structure solution

cDsbD crystals were directly frozen in the nitrogen gas stream. No addition of cryoprotectant was necessary. The first diffraction data of oxidized cDsbD were collected at 90.9 K on beamline X06SA at the Swiss Light Source (Paul Scherrer Institut Villigen, Switzerland) using a MAR CCD image plate at a wavelength of 0.860 Å. This crystal was soaked in saturated cis-Pt(NH₂)₂Cl₂ for around 24 hours before mounting. Data were processed with XDS⁴⁷ to a resolution of 1.1 Å. To obviate a problem with the spindle acceleration the processed data were corrected with the program check_spindleshutter (Kai Diederichs, personal communication). The structure of cDsbD was solved by molecular replacement with AMoRe⁴⁸ using a truncated thioredoxin model⁴⁹ (PDB-code: 2TRX) against 12 to 4 Å data. The truncated search model was aptly modified by visual inspection of a stereo picture of cDsbD superimposed on *E. coli* thioredoxin as published by Kim *et al.*, 2003.²¹ The cDsbD structure was auto-built using ARP/wARP v6⁵⁰ and iteratively rebuilt in O.⁵¹ The structure was first isotropically refined to 1.4 Å using CNS⁴² and then anisotropically refined in SHELXL⁵² to a R-factor of 0.148 and a free R-factor of 0.175 (Table 1).

Since the oxidized cDsbD dataset exhibits photo reduction of the disulfide bridge (see Results and Discussion), a second dataset was collected using an aluminium filter (reducing intensity to 70.3 % of the original value) with 0.751 Å wavelength and at 98.2 K temperature. Oxidized cDsbD data were processed with DENZO and SCALEPACK⁵³ to 1.65 Å, respectively.

Diffraction data for TCEP-reduced cDsbD were collected at a temperature of 100 K with a wavelength of 1.000 Å. Data were processed DENZO and SCALEPACK to a resolution of 1.3 Å.

A second TCEP-reduced crystal was soaked for ten minutes at room temperature in a mixture containing 300 µl precipitant solution (0.1 M ammonium acetate, 0.2 sodium acetate, 0.1 M sodium iodide pH 4.6, 40 % PEG 4K and 3 mM TCEP HCl) and 167.5 µl titration solution (0.3 M HEPES base, 0.1 M NaI, 40 % PEG 4K and 3 mM TCEP HCl) with the final pH of 7.0. Diffraction data for TCEP-reduced and pH shifted cDsbD (cDsbD_{red/pH7}) were collected at a temperature of 100 K with a wavelength of 0.9718 Å. The dataset was processed with DENZO and SCALEPACK to a resolution of 0.99 Å. All cDsbD crystals (oxidized and TCEP-reduced) belong to space group P2₁2₁2₁ and contain one molecule per asymmetric unit (Table 1).

The position of iodide ions from NaI (in the model of cDsbD_{ox}, cDsbD_{red} and cDsbD_{red/pH7}) were identified by analysis of Bijvoet difference Fourier map taking also in account of the environment of the major difference peaks.

Stereochemical analysis

The stereochemistry of all four cDsbD structures was checked with WHAT_CHECK⁵⁴ and PROCHECK.⁵⁵ The photo-reduced and the pH shifted TCEP reduced structures were additionally checked with the Protein Anisotropic Refinement Validation and Analysis Tool (PARVATI⁵⁶, <http://www.bmsc.washington.edu/parvati/parvati.html>). All structural figures were prepared using PyMOL⁵⁷ (<http://www.pymol.org>).

Analysis of the disulfide opening

The opening of the active site disulfide bridge was analysed by partitioning the cDsbD_{pr}-dataset into eight reflection files. In the first reflection file 150 diffraction images were included. An increment of 50 frames was used for every additional reflection file. Every dataset was then independently refined with CNS⁴² and van der Waals interactions between the two sulfurs of Cys461 and Cys464 were made to be ignored. For each model the S-S

distance was measured using the program O.⁵⁸

Acknowledgements

This project was funded by the Schweizerische Nationalfonds, the ETH Zurich and the University of Zurich within the framework of the NCCR Structural Biology program. Data collection for this work was performed at the Swiss Light Source, Paul Scherrer Institut, Villigen, Switzerland. We wish to thank the staff of beamline X06SA for excellent support in X-ray data collection. Ch.U.S. and G.C. are grateful to Beat Blattman for help in crystal screening, to Christophe Briand for help with synchrotron data collection and to Kai Diederichs for providing us with the check_spindleshutter program. Ch.U.S. would like to thank Daniel Frey and Heinz Gut for helpful discussions.

Figure 1. Biophysical properties of cDsbD. **(A)** GdmCl-induced folding and unfolding transitions of oxidized (circles) and reduced (squares) cDsbD at 25°C and pH 7.0. Unfolding (filled symbols) and refolding (open symbols) were followed by the fluorescence at 345 nm (excitation at 280 nm). Original data were evaluated according to the two-state model and normalized. Solid and dashed lines represent the fit for cDsbD_{ox} and cDsbD_{red}, respectively. The obtained m-values of 15.9(± 1.1) kJ mol⁻¹ M⁻¹ and 17.5(± 1.9) kJ mol⁻¹ M⁻¹ and ΔG of -43.9(± 2.9) kJ mol⁻¹ and -45.5(± 5.0) kJ mol⁻¹ for the oxidized and reduced forms, respectively, are very similar. **(B)** pH-dependence of the active site Cys461 reactivity with IAM. The apparent second-order rate constants (k_{IAM}) were determined by HPLC analysis as described in Methods. **(C)** The pH-dependence of the ionization of the Cys461 thiol of cDsbD (circles) and cDsbD-Cys464Ser (squares). The thiolate-specific absorbance was monitored at 240 nm and the fraction of the thiolate anion was calculated as described in Methods. The fit (solid line) yields a p*K_a* value of 9.4 for cDsbD and 9.3 for cDsbD-Cys464Ser. **(D)** Very low reactivity of cDsbD with DTT at 25°C and pH 7.0. The reduction of cDsbD by DTT was performed under pseudo-first order conditions with initial concentrations of 5 μM for cDsbD_{ox} and 1 mM for DTT. The amounts of the reduced and oxidized cDsbD species after different incubation times were quantified by reversed-phase HPLC. The fit (solid line) yields a pseudo-first order rate constant of 0.0154 s⁻¹ that corresponds to a second-order rate constant of 15.4 M⁻¹s⁻¹.

3.4 Rapid reduction of DsbG by nDsbD (unpublished results)

To gain the complete picture on the kinetics of the disulfide exchange reactions performed by nDsbD, we also determined kinetic parameters of the reduction of DsbG by nDsbD. As in the case of DsbC ($3.9 \times 10^6 \text{ M}^{-1}\text{s}^{-1}$), the reaction is extremely fast, with a rate constant of $1.9 \times 10^6 \text{ M}^{-1}\text{s}^{-1}$ (Fig. 10, 11). To test whether the fast electron transfer from nDsbD to DsbC or DsbG is due to their dimerization state, we measured kinetics of the disulfide exchange between

Figure 10. Reduction of DsbG by nDsbD. (His)₆-tagged DsbG was overexpressed and purified as described (Bessette *et al.*, 1999). The kinetics of the reduction of DsbG (1 μM) by nDsbD (1 μM) were monitored at 25°C by the change in DsbG fluorescence at 340 nm using stopped-flow mixing in an Applied Photophysics SX-17MV instrument (1:1 mixing ratio). Measurements were performed in 100 mM sodium phosphate, 0.1 mM EDTA, pH 7.0. Data from 20 independent measurements were averaged and evaluated according to second order kinetics. The fit (red solid line) yields a rate constant of $1.9 \times 10^6 \text{ M}^{-1}\text{s}^{-1}$. Rate constant for the reverse reaction was calculated from the equilibrium constant ($K_{eq} = 3000$) for the reduction of DsbG by nDsbD.

nDsbD and the isolated catalytic domain of DsbC (DsbC-C) or DsbG (DsbG-C). Reduction of DsbG-C by nDsbD proved to be 10 times slower ($2.0 \times 10^5 \text{ M}^{-1}\text{s}^{-1}$, Fig. 12 B) than the reaction between DsbG and nDsbD, which could be caused by lowered effective concentration of the active site cysteines in DsbG-C compared to DsbG. Surprisingly, disulfide exchange between DsbC-C and nDsbD is an extremely slow process with a second-order rate constant of $3.6 \times 10^3 \text{ M}^{-1}\text{s}^{-1}$ (Fig. 12 A, the data were provided by Patrick Frei). Thus, dimerization of DsbC is likely required for its efficient reduction by nDsbD *in vivo*, rather than for protection active sites of DsbC from DsbB-mediated oxidation as it was proposed earlier (Bader *et al.*, 2001). Overall, through dimerization DsbC gains the second binding site that interacts with the same nDsbD molecule (Fig. 8B) (Haebel *et al.*, 2002), which dramatically increases the affinity.

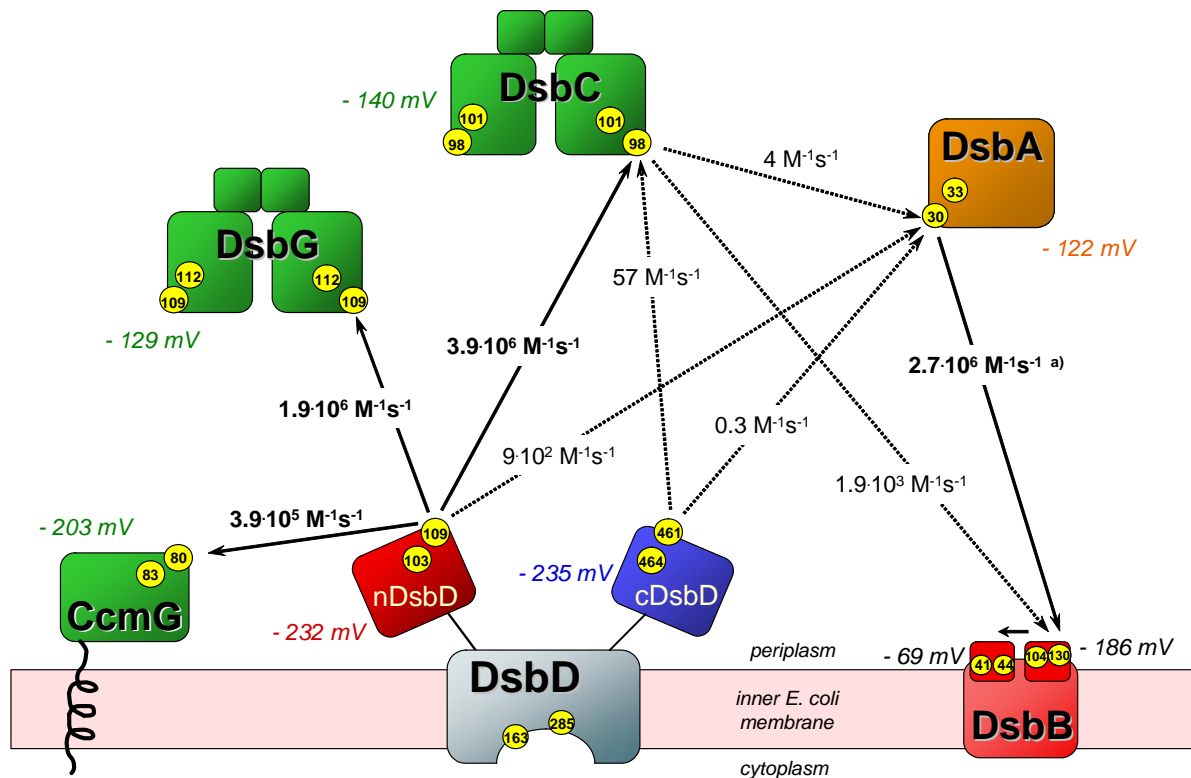

Figure 11. Complete kinetic picture of functional and non-functional disulfide exchange reactions between components of the oxidizing DsbB pathway and the reducing DsbD pathway. Arrows indicate the direction of two-electron transfer. Functional disulfide exchange reactions (solid bold arrows) have second-order rate constants above $10^5 \text{ M}^{-1}\text{s}^{-1}$, while non-functional reactions (dotted arrows) are 10^2 - 10^7 -fold slower. ^{a)} (Grauschopf *et al.*, 2003)

Figure 12. Reduction of DsbC-C and DsbG-C by nDsbD. DsbC-C and DsbG-C were overexpressed and purified according to the protocol used for the wild-type proteins (Bessette *et al.*, 1999; Maskos *et al.*, 2003). **A.** The kinetics of the reduction of DsbC-C_{ox} (3.5 μM) by nDsbD_{red} (3.5 μM) were measured by reversed-phase HPLC as described for DsbC (Rozhkova *et al.*, 2004). **B.** Reduction of DsbG-C_{ox} (1 μM) by nDsbD_{red} (1 μM) was followed by stopped-flow as described above for DsbG. All measurements were performed in 100 mM sodium phosphate, 0.1 mM EDTA, pH 7.0. Data were evaluated according to second-order kinetics. The fit (red solid line) yields rate constants of $3.6 \times 10^3 \text{ M}^{-1}\text{s}^{-1}$ and of $2.0 \times 10^5 \text{ M}^{-1}\text{s}^{-1}$ for the reduction of DsbC-C and DsbG-C, respectively. Rate constants for the reverse reactions were calculated from the equilibrium constants for the reduction of DsbC ($K_{\text{eq}} = 1300$) or DsbG ($K_{\text{eq}} = 3000$) by nDsbD, respectively.

4. Oxidative protein folding in eukaryotes versus *E. coli*: analogies and differences

In eukaryotes, folding and assembly of secretory and membrane proteins containing disulfide bonds take place in the endoplasmic reticulum (ER). The environment of the ER lumen provides the pH and redox conditions required for folding. A growing family of ER thioredoxin-like oxidoreductases is thought to be responsible for the formation of native disulfide bonds in the ER. Protein disulfide isomerase (PDI) is the most prominent and best characterized member of this family and an essential enzyme in all eukaryotes. PDI was discovered by Anfinsen's group in early 1960's as a component of microsomal extracts that assisted the refolding of RNase A and lysozyme (Goldberger *et al.*, 1963, 1964). PDI is composed of four thioredoxin-like domains (**a-b-b'-a'**), followed by the acidic **c** domain. There is an extensive internal sequence similarity between the **a** domain and the **a'** domain as well as between the **b** domain and the **b'** domain. The two redox active site sequences of PDI (C-G-H-C) are located in the **a** and **a'** domains, and the active site cysteine residues are required for PDI activity (Laboissiere *et al.*, 1995; Vuori *et al.*, 1992). PDI is a multifunctional enzyme capable of catalyzing formation, reduction and isomerization of disulfide bonds in proteins *in vitro*. The oxidative activity of PDI is also established *in vivo*. For example, oxidative folding of the secretory marker protein carboxypeptidase Y (CPY) depends on direct oxidation by PDI in yeast (Frand and Kaiser, 1999; Holst *et al.*, 1997). The capture of mixed-disulfides between PDI and CPY indicates direct thiol-disulfide exchange between PDI and the substrate protein in the ER (Frand and Kaiser, 1999). Upon oxidation of thiols in substrate proteins, PDI becomes reduced and must be re-oxidized. Since glutathione is the major redox buffer in the ER, and the ratio of reduced (GSH) to oxidized (GSSG) glutathione in the ER (between 1:1 and 3:1) provides optimal conditions for oxidative refolding of proteins *in vitro*, it was believed that glutathione was responsible for re-oxidation of the PDI active sites. However, elimination of glutathione from the yeast cell by removal of the enzyme involved in the first step of synthesis, γ glutamylcysteine synthetase, did not prevent disulfide bond formation, but rendered the cells more prone to hyperoxidation, suggesting that glutathione functions as a net reductant in the ER (Cuozzo and Kaiser, 1999). Both genetic and biochemical approaches in yeast showed that the conserved membrane-associated ER protein Ero1 is responsible for the oxidation of PDI (Chakravarthi and Bulleid, 2004; Frand and Kaiser, 1998; Tu *et al.*, 2000; Tu and Weissman, 2002). Defects in Ero1 lead to a lack of disulfide bond formation, whereas overexpression of Ero1 accelerates the rate of

oxidative protein folding and the acquisition of a native structure, demonstrating that Ero1 is an essential component of the oxidative folding machinery (Chakravarthi and Bulleid, 2004; Frand and Kaiser, 1998; Pollard *et al.*, 1998; Sevier and Kaiser, 2002). Ero1 is an FAD-dependent enzyme that is able to oxidize PDI directly through disulfide exchange and pass electrons to the terminal electron acceptor, molecular oxygen (Frand and Kaiser, 1999; Tu *et al.*, 2000). Ero1 can catalyze oxidation of PDI also under anaerobic conditions, indicating that alternative electron acceptors could be used in the absence of oxygen (Sevier *et al.*, 2001). It has been shown that PDI / Ero1-catalyzed disulfide bond formation proceeds independent of glutathione both *in vivo* and *in vitro* (Cuozzo and Kaiser, 1999; Tu *et al.*, 2000). Thus Ero1 and PDI constitute an oxidative pathway (Fig. 13), analogous to the DsbA/B pathway in *E. coli*, that independently of the bulk redox environment catalyzes rapid disulfide formation in eukaryotes. An important implication of this finding is that the flow of oxidizing equivalents

Figure 13. Schematic model of oxidative protein folding in the ER. The formation of disulfide bonds in the ER is catalyzed by PDI and Ero1. Disulfide isomerization may be performed by PDI or some of its homologues that are possibly kept in the active reduced state by GSH or by a not yet identified redox catalyst. (Tu and Weissman, 2004)

in the ER is controlled by the kinetics of the disulfide exchange between proteins rather than by equilibration of protein thiols and disulfides with glutathione redox buffer.

The formation of native disulfide bonds not only involves oxidative pairing of free thiols, but also isomerization of wrongly formed disulfides in proteins with multiple disulfide bonds. Eukaryotic secretory proteins typically contain more disulfide bonds than their prokaryotic counterparts, indicating that there is an even greater need for disulfide bond isomerization function in the ER than in the periplasm. Although many proteins are able to

fold spontaneously in a glutathione buffer in the absence of oxidoreductases, the folding rate is dramatically increased in the presence of PDI (Weissman and Kim, 1993). In addition to a kinetic advantage, the catalyzed reduction or isomerization of disulfide bonds in proteins has the advantage that the enzymes favour the formation of native over non-native disulfides. The most obvious candidate for the role of the disulfide isomerase in the ER is PDI that is by far the most active disulfide isomerase *in vitro*. An attractive model is that PDI catalyzes all types of reactions important for oxidative protein folding *in vivo*, namely disulfide bond formation, reduction and isomerization. Combination of the oxidase, the reductase and the isomerase activities requires that redox active sites of PDI would either alternatively exist in the oxidized or reduced state, or that one of them would be kept in the oxidized state and the other in the reduced state *in vivo*. Recently, Tai and Rapoport (2005) showed that Ero1 oxidizes only the **a'** domain (Tsai and Rapoport, 2002). Moreover, Ero1 seems to be more efficient in oxidizing substrate-associated PDI compared to free PDI (Tsai and Rapoport, 2002). This would prevent futile redox cycles of PDI in the absence of substrate, in which free oxidized PDI would be reduced by GSH. Since the **a** domain is not a substrate of Ero1, it could be kept in reduced state for example by the glutathione redox buffer and function as an isomerase or a reductase. This assumption is consistent with the observation that PDI is partially reduced in the ER of yeast (Xiao *et al.*, 2004).

Another possibility is that individual members of the PDI family might be dedicated to the catalysis of disulfide bond formation, reduction or isomerization *in vivo*, just as DsbA and DsbC work in separate pathways to catalyze disulfide bond formation and isomerization in the bacterial periplasm. In this context, it is not surprising that there are four PDI homologues in the ER of yeast and dozens more are found in higher eukaryotes. Several of these oxidoreductases exist in a predominantly reduced form in the cell and therefore could act as substrate-specific reductases or isomerases (Mezghrani *et al.*, 2001; Tu and Weissman, 2004). In yeast, one or more of the PDI homologues appeared to contribute to the maturation of CPY that requires disulfide bond isomerization *in vitro* (Xiao *et al.*, 2004).

Since disulfide bond isomerization can be catalyzed by oxidoreductases only in reduced state, there must be a reductive pathway in the ER. The existing data indicate that glutathione plays a role in the formation of native disulfide bonds in the ER (Chakravarthi and Bulleid, 2004; Jessop *et al.*, 2004). Chakravarthi and Bulleid (2004) showed that a normal level of intracellular glutathione is required to prevent the formation of non-native disulfide bonds during the post-translational folding in the ER of human tissue type plasminogen activator that contains 17 disulfide bonds. The detection of a mixed disulfide between

glutathione and Erp57, an analogue of PDI, led to the conclusion that GSH can reduce the ER oxidoreductases directly (Jessop *et al.*, 2004). However, these data do not prove that the direct reduction of the ER oxidoreductases by glutathione is the only existing or main reductive pathway in the ER. It could well be that glutathione contributes to the overall redox equilibrium in the eukaryotic cell, rather than directly participating in the disulfide reduction in the ER proteins. In this case, the reducing equivalents required for the disulfide bond isomerization in the ER could come through a separate enzyme-catalyzed pathway, analogous to the reductive DsbC/DsbD pathway in *E. coli*. In this model, glutathione (or another low molecular weight reductant) could serve as a source of reducing power in the eukaryotic cell that would be transferred by a redox catalyst to the ER oxidoreductases (Fig. 13).

Dependence of the formation of native disulfides in proteins both in prokaryotes and eukaryotes on oxidative and reductive reactions, and therefore requirement of catalytic pathways for maintaining the appropriate redox state of the oxidoreductases, raises the question of how the two seemingly opposing pathways can coexist within the same intracellular compartment. Applying the principles discovered in prokaryotes, the segregation of the oxidative and the reductive pathways could be explained by kinetic barriers between the two pathways. Indeed, fast and specific oxidation of PDI by Ero1 well explains effective disulfide bond formation in the ER in the presence of GSH. On the other hand, the inability of Ero1 to oxidize the a domain and some of PDI homologues (Mezghrani *et al.*, 2001; Tu and Weissman, 2004) can cause their accumulation in the reduced state such that they function as disulfide isomerases or reductases in the presence of glutathione redox buffer. However, the reduction of these enzymes by glutathione may be not rapid enough to support protein folding in the cell, and not yet identified redox catalyst(s), analogous to DsbD, could be required. In this context, complete kinetic analysis of the possible disulfide exchange reactions between the ER components involved in native disulfide bond formation would provide important information about the intracellular role of glutathione and the mechanism of oxidative protein folding in eukaryotes.

5. Outlook

The most intriguing and difficult question about the catalytic mechanism of DsbD is electron transfer across the inner membrane. Despite the intensive studies on DsbD during last 10 years, its TM domain remains poorly characterized. For example, such a basic property as the redox potential is not yet determined. We do not know whether DsbD needs a co-factor for its function, and if not, how could a single pair of cysteine residues be sufficient for electron transfer across ~ 60 Å membrane space? It is also not clear, which cysteine in the TM domain mediates the disulfide exchange between the TM domain and cDsbD.

One of the difficulties in the characterizing the disulfide exchange reaction between DsbD domains is the fact that the wild type domains of DsbD show no change in fluorescence upon reduction/oxidation. To solve this problem, we engineered a Trp-variant of cDsbD (cDsbD-Y457W), which doubles its fluorescence signal upon reduction. This amino acid replacement does not affect stability, redox potential and reactivity of the protein. Based on the Y457W mutation, spectroscopically active DsbD constructs can be designed. For example, a truncated DsbD variant lacking nDsbD and bearing the Y457W replacement would be a useful tool for investigation of the disulfide exchange between the TM domain and cDsbD. A fusion construct with nDsbD and cDsbD-Y457W linked *via* a flexible linker of different length can be used to estimate the rate of the intramolecular disulfide exchange between the periplasmic domains of DsbD and their effective concentrations in the context of full-length DsbD.

In vitro reconstitution of the entire electron flow from NADPH, thioredoxin reductase and thioredoxin to DsbC *via* DsbD is an important and necessary proof of the proposed mechanism. However, the reconstitution could not be achieved simply by mixing the purified components in solution, as there is comparably fast direct electron transfer from thioredoxin to nDsbD, cDsbD or DsbC (circumventing electron flow through the TM domain). Incorporation of DsbD into liposomes thus seems to be a very attractive approach. First of all, the membrane protein would be in the environment close to the natural and could adopt proper conformation. Second, it would allow separation of the cytosolic and periplasmic components of the pathway by the membrane and therefore would exclude the above-mentioned side reactions. Third, presence of the membrane gives a possibility to adjust the pH and ionic strength conditions corresponding to the cytosol and the periplasm.

Finally, determination of the X-ray structure of full-length DsbD is of high interest. The X-ray structure of the nDsbD-SS-cDsbD mixed disulfide, which was determined in this work, could be used to solve the structure of DsbD through molecular replacement.

6. Curriculum vitae

Name: Anna Rozhkova
Date of birth: March 27, 1979
Place of birth: Moscow
Nationality: Russian Federation

Education:

1985-1995: School, Moscow, Russian Federation

1995-2000: Studies at Moscow State University, Russian Federation

2000: Diplom in Biochemistry

2000-2001: Trainings in Biophysics in group of Prof. Victor Tsetlin, Institute of Bioorganic Chemistry, RAS, Moscow, Russian Federation

2001-2005: PhD thesis at the Institut für Molekularbiologie und Biophysik, Eidgenössische Technische Hochschule Zürich, Switzerland, under supervision of Prof. Rudi Glockshuber

7. Acknowledgments

First of all, many thanks to my supervisor Prof. Rudi Glockshuber for the opportunity to work on this PhD project, for all ideas and discussions, and for being a perfect Boss.

Thanks to Prof. Linda Thöny-Meyer for waking up my interest to the cytochrome *c* maturation.

Dr. Guido Capitani, Christian Stirnimann, and Prof. Markus Grütter, I thank for the fruitful collaboration in crystallization and structure determination.

I also thank all members of the group of Prof. Glockshuber. I say my especial thanks to Dr. Ulla Grauschopf for the excellent permanent help during the whole PhD work, for the perfect advises and suggestions, for all the knowledge, shared with me, and for critical reading of this thesis. Thanks to Patrick Frei and Goran Malojčić for many fruitful discussions and collaboration. I thank Andrea Fritz for cloning of some constructs and for being a source of sparkling life energy in the lab. Thanks to Dr. Eva Künnemann-Zobeley for the introduction into the stopped-flow technique. Dr. Michael Vetsch and Prof. Eilika Weber-Ban, I thank for the introduction into kinetics, for the help with data analysis, and for being my co-examiner. Thanks to Dr. John Grimshaw for critical reading of this thesis.

Finally, I would like to thank the members of the Protein Service Lab, Dr. René Brunisholz for a lot of help with HPLC experiments and for Edman sequencing, and Helene Rechsteiner for MALDI-MS measurements.
