

DISS. ETH NO. 24264

N-LINKED PROTEIN GLYCOSYLATION

Functional characterization of the eukaryotic oligosaccharyltransferases

A thesis submitted to attain the degree of
DOCTOR OF SCIENCES of ETH ZURICH
(Dr.sc. ETH Zurich)

presented by
KRISTINA POLJAK

MSc. in Molecular Biology, University of Zagreb, Croatia
MSc. in Bioindustrial Techniques, University of Orleans, France

born on 04.11.1987
citizen of Republic of Croatia

accepted on the recommendation of
Prof. Dr. Markus Aebi
Prof. Dr. Kaspar Locher
Prof. Dr. Yves Barral

2017

Acknowledgements

First and foremost, I would like to thank my thesis supervisor Prof. Dr. Markus Aebi for opening the doors of ETH Zurich by offering me an internship followed by an encouragement to do my PhD in his group as well. Not only could I profit highly from his guidance and extensive knowledge but I also appreciated greatly the freedom I enjoyed in pursuing the research described in this thesis as I saw fit.

I thank the members of my PhD committee, Prof. Dr. Kaspar Locher, Prof. Dr. Yves Barral and Prof. Dr. Reid Gilmore, for fruitful discussions and useful input into my research during our yearly meetings. I am especially thankful to Prof. Dr. Yves Barral and his group members for experimental support and providing valuable expertise when my experiments asked for it.

I would also like to thank all current and former members of the Aebi group for their help, discussions and generally a nice working atmosphere. Special thanks go to Elsy, Martina, Nathalie, Susanna and Julia for sharing the good and less good experiences throughout our joint time in the lab, Dr. Robert Gauss for his input and good discussions, Dr. Jörg Breitling for entrusting his *Trypanosoma brucei STT3* project to me, and Carole Grädel for the hard work during her semester project.

I owe gratitude to the Functional Genomics Center Zurich members, especially Dr. Nathalie Selevsek who taught me everything I know about mass spectrometry, patiently answered all my questions and supported me during the last two years of my thesis.

I would like to thank Melina, for her support, patience and understanding during difficult times and her cheers during the good ones. You indebt me to always be the best version of myself and I will always be grateful for that. Special thanks goes to my brother Mirko, who has never seized to amaze me ever since we were kids. Thank you for making me grow up with a love of science, you were and always will be an inspiration.

My deepest gratitude goes to the most basic source of my life, my parents to whom I dedicate this thesis. Their support and love has been unconditional, they have given up many things for me to be at ETH Zurich and I would like to thank them in Croatian now.

Dragi roditelji, dugujem vam svoju najdublju zahvalnost na ljubavi, razumijevanju i svakodnevnim odricanjima kroz koje ste omogućili ovaj rad kojeg posvećujem vama. Hvala vam na bezgraničnom ponosu i pouzdanju na mom putu od prvoškolske klupe do doktorata znanosti. Vaša bezuvjetna ljubav i podrška su me pratili u svim trenucima i bez vas sigurno ne bih bila tu gdje jesam. Volim vas puno.

Summary

N-linked protein glycosylation is a highly conserved and an essential protein modification found throughout the three domains of life. In animal, plants and fungi the preassembled oligosaccharide consisting of two N-acetylglucosamines, nine mannoses and three glucoses is transferred *en bloc* from the lipid carrier to the asparagine side chains within N-X-S/T consensus sequences on nascent polypeptides in the lumen of the endoplasmic reticulum (ER). This transfer is catalysed by the central enzyme of the pathway, oligosaccharyltransferase (OST). After the transfer, the oligosaccharide is modified in a species, tissue and cell-specific manner, resulting in a vast array of different glycan structures.

The first chapter of this thesis offers an overview of the N-linked protein glycosylation pathway. The biosynthesis of the lipid-linked oligosaccharide (LLO) is described first followed by the description of the OST and the biological relevance of this modification. Furthermore, diverse analytical tools and methods used to help explore and characterize the pathway, with the emphasis on the quantitative mass spectrometric approaches, are discussed.

In the second chapter, we coupled parallel reaction monitoring (PRM) mass spectrometry method to stable isotope labelling (SILAC) to measure N-linked glycosylation occupancy of yeast glycoproteins. The OST from yeast *Saccharomyces cerevisiae* is a multi-subunit protein complex. Using our SILAC-PRM method, we further explored the roles of the two non-essential OST subunits, Ost3p and Ost6p, and provided insights into the mechanisms that regulate site-specific N-glycosylation by the OST.

The investigation of the substrate specificity of the single subunit OSTs from *Trypanosoma brucei* is reported in chapter three. The effect of different oligosaccharide substrate structures on the function of *Tb*OSTs was studied in yeast using genetic manipulations of the LLO biosynthesis. Additionally, structure to function coupled to SILAC-PRM analyses were performed to identify regions in the OST proteins that influence the specificity of different paralogues for the LLO as well as for the polypeptide substrate.

In order to functionally characterize WBP1, an essential subunit of yeast OST, we performed a mutagenesis study reported in the fourth chapter. We have used reverse genetics approach for generating point mutations in the conserved residues of Wbp1p and identified novel mutants that alter glycosylation by influencing complex assembly.

Concluding remarks and future perspectives complete the thesis in the fifth chapter.

Zusammenfassung

Die Glykosylierung von Asparaginen ist eine hoch konservierte und essentielle Modifikation von Proteinen, die in allen Domänen des Lebens gefunden wird. In Tieren, Pflanzen und Pilzen wird das zuvor gebildete Oligosaccharid, bestehend aus zwei N-Acetylglucosaminen, neun Mannosen und drei Glukosen, vom Lipidträger zu den Asparagin Seitenketten in N-X-S/T Sequenzmotiven auf Polypeptide im Lumen des Endoplasmatischen Retikulums (ER) übertragen. Diese Übertragung wird durch das zentrale Enzym der Asparagin-gebundenen Proteinglykosylierung, Oligosaccharyltransferase (OST) katalysiert. Nach der Übertragung wird das Oligosaccharid in einer spezie-, gewebe- und zell-spezifischen Weise modifiziert, was zu einer Vielzahl unterschiedlicher Glykanstrukturen führt.

Das erste Kapitel dieser Doktorarbeit bietet einen Überblick über die Asparagin-gebundene Proteinglykosylierung. Die Biosynthese des lipidgebundenen Oligosaccharids (LLO) wird zuerst geschildert, gefolgt von der Beschreibung der OST und der biologischen Relevanz dieser Modifikation. Darüber hinaus werden diverse analytische Instrumente und Methoden zur Erforschung und Charakterisierung der Asparagin-gebundenen Proteinglykosylierung diskutiert, mit Schwerpunkt der verschiedenen quantitativen Massenspektrometrie-Methoden.

Im zweiten Kapitel koppelten wir stabile Isotopen-Markierung von Aminosäuren in Zellkultur (SILAC) mit einer parallelen Reaktions-Monitoring (PRM) Methode, um die N-Glykosylierung von Hefeglykoproteinen zu messen. Die OST der Hefe *Saccharomyces cerevisiae* ist ein Proteinkomplex mit mehreren Untereinheiten. Mit unserer SILAC-PRM Methode haben wir die Rollen der beiden nicht-katalytischen OST-Untereinheiten Ost3p und Ost6p weiter untersucht und Einblicke in die Mechanismen gegeben, welche die ortsspezifische N-Glykosylierung durch die OST regulieren.

Die Untersuchung der Substratspezifität der einzelnen Untereinheiten der OSTs von *Trypanosoma brucei* wird in Kapitel drei beschrieben. Die Wirkung unterschiedlicher Oligosaccharid-strukturen auf die Funktion von TbOSTs wurde in Hefe unter Verwendung genetischer Manipulationen der LLO-Biosynthese untersucht. Zusätzlich wurden Struktur und Funktionsanalysen, gekoppelt mit SILAC-PRM Analysen durchgeführt, um Bereiche in den OST-Proteinen zu identifizieren, die die Spezifität der verschiedenen Paralogen für das LLO sowie für das Polypeptidsubstrat beeinflussen.

Um WBP1, eine essenzielle Untereinheit der Hefe OST, funktionell zu charakterisieren, haben wir im vierten Kapitel eine Mutagenesestudie durchgeführt. Wir haben einen reversen Genetik-Ansatz zur Erzeugung von Punktmutationen in den konservierten Resten von Wbp1p verwendet und neue Allelen identifiziert, die die Glykosylierung durch Beeinflussung des OST Aufbaus verändern.

Schlussbemerkungen und Zukunftsperspektiven vervollständigen die Dissertation im fünften Kapitel.

Abbreviations

OST	oligosaccharyltransferase
LLO	lipid-linked oligosaccharide
Dol	dolichol
P	phosphate
PP	pyrophosphate
Hex	hexose
HexNAc	N-acetylhexosamine
Glc	glucose
Gal	galactose
Man	mannose
GlcNAc	N-acetylglucosamine
EndoH	endo- β -N-acetylglucosaminidase
SRM	selected reaction monitoring
PRM	parallel reaction monitoring
SILAC	stable isotope labelling with amino acids in cell culture
HPLC	high-pressure liquid chromatography

Chapter 1

Introduction to N-linked Protein Glycosylation

1. Lipid linked oligosaccharide biosynthesis

N-linked glycosylation is a highly conserved posttranslational modification of proteins. The initial steps of N-linked protein glycosylation are carried out on the endoplasmic reticulum (ER) membrane in eukaryotes and periplasmic membrane in archaea and bacteria. The assembly of the lipid linked oligosaccharide (LLO) is the first step of N-linked glycosylation followed by the transfer of the oligosaccharide to the dedicated asparagine residues of nascent polypeptides in the ER. The LLO assembly is characterized by the use of dolichyl-pyrophosphate (Dol-PP) as a carrier for oligosaccharide assembly and the bipartite localisation of the pathway. The process is catalysed by a panel of membrane-bound glycosyltransferases belonging to the *ALG* family (asparagine-linked-glycosylation) leading to the assembly of a Dol-PP-linked precursor oligosaccharide. The LLO assembly is initiated at the cytoplasmic side of the ER membrane and only after the LLO intermediate has been flipped, continues at the luminal side (Helenius & Aebi 2004; Breitling & Aebi 2013)(Figure 1).

1.1. Lipid carrier

The LLO biosynthesis is characterized by the participation of a special carrier lipid dolichol that belongs to a group of polyisoprenoid molecules with a saturated α -isoprene unit. The initial steps in dolichol biosynthesis are the same as for sterols and ubiquinones and start with the mevalonic acid pathway (Chojnacki & Dallner 1988). A precisely coordinated mechanism regulates the biosynthesis of the mevalonic acid pathway intermediates that are precursors in biosynthesis of many essential molecules such as sterols (especially ergosterol in yeast and cholesterol in animals) involved in membrane structure, and dolichol, required for glycoprotein synthesis (Goldstein & Brown 1990). The pathways diverge after the synthesis of farnesyl-pyrophosphate, which is a substrate of either *cis*-prenyltransferase that leads to dolichol biosynthesis, or squalene synthase that leads to ergosterol biosynthesis (Adair & Cafmeyer 1987; Robinson et al. 1993).

Farnesyl-pyrophosphate is elongated by *cis*-prenyltransferase that sequentially adds activated isopentenyl-pyrophosphate units in species-dependent manner, where different organisms have distinct dolichol chain length. Mammalian cells have dolichols that consist of 18-21 isoprene units, 15-16 isoprene units were described in dolichols from *Saccharomyces cerevisiae* while shorter dolichols with 11-12 isoprene units are found in the protozoan parasite *Trypanosoma brucei* (Jung & Tanner 1973; Rip et al. 1985; Adair & Cafmeyer 1987; Löw et al. 1991; Breitling & Aebi 2013). In the final steps of dolichol biosynthesis, the polyprenyl-pyrophosphate product is first dephosphorylated and then reduced by an NADPH dependent α -reductase, encoded by *DFG10* in yeast (Sagami et al. 1993;

Szkopińska et al. 1993; Schenk et al. 2001; Frank & Waechter 1998; Cantagrel et al. 2010). Since dolichol was detected in the cells deleted of *DFG10*, an alternative pathway for de novo synthesis of dolichol was suggested as well (Cantagrel et al. 2010). Dolichol is subsequently phosphorylated by CTP-dependent dolichol kinase, encoded by *SEC59* in yeast, to form dolichyl-phosphate (Dol-P) (Heller et al. 1992; Shridas & Waechter 2006). The Dol-P lipid carrier is then ready to serve as a carrier for sugar residues used in N-linked glycosylation, as well as O-mannosylation and glycosylphosphatidylinositol (GPI) anchor synthesis (Rip et al. 1985).

1.2. Sugar donors for LLO biosynthesis

The three main carbohydrate components of LLOs are N-acetylglucosamine (GlcNAc), mannose (Man) and glucose (Glc). These sugar residues are added to the LLO in a stepwise manner, starting at the cytoplasmic side of the ER membrane where sugar residues are added from soluble, nucleotide activated sugar donors, and continues in the lumen of the ER where Dol-P linked sugars serve as substrate donors in LLO biosynthesis.

The biosynthesis of GDP-Man, UDP-GlcNAc and UDP-Glc starts with Glc-6-phosphate. In the case of first two sugar donors, GDP-Man and UDP-GlcNAc, Glc-6-phosphate is enzymatically isomerized to form fructose-6-phosphate (Dickinson 1991). GDP-Man is then synthesized in three steps from fructose-6-phosphate while biosynthesis of UDP-GlcNAc includes four steps (Hashimoto et al. 1997; Milewski et al. 2006). In the biosynthesis of UDP-Glc Glc-6-phosphate is first converted to Glc-1-phosphate followed by formation of UDP-Glc (Boles et al. 1994; Daran et al. 1995).

Sugars bound to Dol-P serve as substrates for LLO assembly in the ER luminal phase. Here, nucleotide activated sugars, GDP-Man and UDP-Glc, serve as donors for the biosynthesis of Dol-P-Man and Dol-P-Glc, respectively. Both reactions take place at the cytoplasmic side of ER membrane. Dol-P-Man is synthesized by the essential Dol-P-Man synthase, encoded by *DPM1* in budding yeast (Orlean 1990), while the fission yeast and mammalian enzymes are a complex of three proteins, where the homologue of Dpm1p is the catalytic subunit (Maeda et al. 1998; Maeda et al. 2000). Dol-P-Glc is generated by the non-essential Dol-P-Glc synthase, encoded by *ALG5* (te Heesen et al. 1994). As Dol-P bound sugars are synthesized on the cytoplasmic side, in order to participate in LLO assembly they need to be translocated to the luminal side of the ER membrane. Although proteins responsible for translocation have not been identified so far, the Dol-P-Man flipping was characterized to be ATP-dependent and stereoselective (Sanyal & Menon 2010).

1.3. The assembly of the LLO

Fully assembled LLO contains two N-acetylglucosamine, nine mannose and three glucose residues. Asparagine linked glycosylation (ALG) pathway genes encode for a series of enzymes involved in LLO biosynthesis responsible for the stepwise build-up of the $\text{GlcNAc}_2\text{Man}_9\text{Glc}_3$ LLO (Figure 1).

Figure 1. The N-linked glycosylation pathway.

Biosynthesis of the $\text{Dol-PP-GlcNAc}_2\text{Man}_9\text{Glc}_3$ LLO precursor is a sequential process catalysed by glycosyltransferases encoded by *ALG* genes. The assembly is initiated at the cytoplasmic side of the ER membrane, after the flipping of the intermediate $\text{Dol-PP-GlcNAc}_2\text{Man}_5$, it continues at the luminal side. The final *en bloc* transfer of the fully assembled LLO to the asparagine within the N-X-S/T sequon of nascent polypeptide is catalysed by the OST.

The build-up of the LLO starts at the cytoplasmic side of the ER membrane and is catalysed by cytosolic enzymes that produce $\text{Dol-PP-GlcNAc}_2\text{Man}_5$ from the soluble nucleotide activated sugar donors (Figure 1). Enzymes involved in this stepwise cytoplasmic biosynthesis are organized into two functional complexes proposed to facilitate efficient glycosylation by permitting a flux of LLO intermediates between successive active sites (Noffz et al. 2009; Lu et al. 2012). The initial step of LLO assembly is catalysed by the UDP-GlcNAc utilizing Alg7/Alg13/Alg14 protein complex where the essential ALG7 encoded N-acetylglucosaminyl phosphate transferase is responsible for the transfer of the GlcNAc-phosphate to the Dol-P lipid carrier to form Dol-PP-GlcNAc (Rine et al. 1983; Noffz et al. 2009). Alg7p is a known target of the drug tunicamycin, frequently used to study the effect of N-linked glycosylation

inhibition on biological processes (Takatsuki et al. 1971; Kukuruzinska & Robbins 1987). The second GlcNAc residue is added to Dol-PP-GlcNAc by Alg13p and Alg14p (Bickel et al. 2005; Chantret et al. 2005) where Alg14p coordinates the recruitments of both Alg7 and Alg13 proteins (Lu et al. 2012). The following steps of cytoplasmic LLO assembly are catalysed by GDP-Man dependent Alg1p/Alg2p/Alg11p complex (X. D. Gao et al. 2004). *ALG1* encoded β -1,4-mannosyltransferase adds the first mannose to Dol-PP-GlcNAc (Couto et al. 1984). Alg2p sequentially adds two branching mannoses, where α -1,3-linked mannose is added first followed by an addition of α -1,6-linked mannose residue (O'Reilly et al. 2006; Kampf et al. 2009). LLO is then elongated by two α -1,2-linked mannoses added by Alg11p to the α -1,3-linked branching mannose residue (Cipollo et al. 2001; O'Reilly et al. 2006). In order to be further elongated, the final product of the *ALG* pathway on the cytoplasmic side, Dol-PP-GlcNAc₂Man₅, of the ER membrane needs to be translocated into the ER lumen. Although not fully understood, the process is substrate specific and mediated by Rft1p in yeast, albeit *in vitro* experiments demonstrated Rft1p-independent flipping as well (Snider & Rogers 1984; Rush & Waechter 1995; Rush et al. 1998; Helenius et al. 2002; Sanyal et al. 2008; Sanyal & Menon 2009). The crystal structure of the LLO flippase PglK from *Campylobacter jejuni* revealed a whip-like mechanism where the lipid tail of the LLO interacts first with the flippase, followed by the pyrophosphate group that pulls along the oligosaccharide. Upon ATP hydrolysis, the conformational change of PglK results in the release of the polar pyrophosphate-oligosaccharide into the aqueous milieu and disengagement of the lipid tail from the PglK (Perez et al. 2015). Compared to bacterial LLOs that contain undecaprenyl-linked oligosaccharide, eukaryotic LLOs have longer polyisoprenoids and do not seem to require ATP in the flipping process; therefore, the flipping mechanism might not be the same (Jung and Tanner 1973; Rip et al. 1985; Adair and Cafmeyer 1987; Sanyal and Menon 2009).

After translocation of Dol-PP-GlcNAc₂Man₅, four mannosyltransferases and three glucosyltransferases are involved in the full assembly of the lipid-linked core oligosaccharide at the luminal side of the ER membrane (Figure 1). Luminal enzymes differ from early *ALG* enzymes in three respects. First, they utilize lipid-bound activated sugars as donor substrates, Dol-P-Man and Dol-P-Glc. Second, they are grouped in GT-C superfamily of inverting enzymes, resulting in α configuration of the added sugar residue (Lairson et al. 2008). Third, the genes encoding for these transferases are not essential for vegetative growth of yeast cells at non permissive temperature, though deletions of late *ALG* genes result in hypoglycosylation of secretory proteins (Huffaker & Robbins 1983; Runge & Robbins 1986; Burda & Aebi 1999). Glycosylation of the LLO at the ER luminal side is initiated by the Alg3, an α -1,3 mannosyltransferase that initiates the LLO b-branch (Figure 1) (Aebi et al. 1996; Sharma et al. 2001). The assembly of the b-branch is then completed by *ALG9* encoded α -1,2 mannosyltransferase (Cipollo & Trimble 2000; Frank & Aebi 2005). In the next step, LLO c-branch is initiated by Alg12 α -1,6 mannosyltransferase and is further elongated by Alg9p, adding the second α -1,2-linked Man residue

(Burda et al. 1999; Cipollo & Trimble 2002; Frank & Aebi 2005). Further steps involve the addition of three glucose residues to LLO α -branch. Alg6 and Alg8 glucosyltransferase transfer the first and the second α -1,3-linked glucose, respectively (Stagljar et al. 1994; Reiss et al. 1996). The final step in LLO synthesis, addition of a third glucose residue in α -1,2 linkage yielding the fully assembled core oligosaccharide, is catalysed by Alg10p (Burda & Aebi 1998).

High substrate specificity of the *ALG* encoded glycosyltransferases for the define LLO intermediates results in ordered built-up of the LLO described above. Therefore, deletions of individual *ALG* genes involved in the luminal LLO assembly result in accumulation of define LLO intermediates allowing for the "genetic tailoring" of the OST substrate (Jakob et al. 1998).

1.4. The dolichol cycle

As mentioned before, Dol-P serves as substrate for the initiating step of N-linked glycosylation and for the biosynthesis of Dol-P bound sugars used in N-linked glycosylation, GPI-anchor biosynthesis and O-mannosylation reactions, and C-mannosylation reaction in mammalian cells. It is therefore not surprising that the availability of Dol-P represents a key factor in the assembly of the LLO in eukaryotes. There are several ways of Dol-P generation (Schenk et al. 2001). (1) Dol-P is generated *de novo* on the cytoplasmic side of the ER by the biosynthetic pathway described above. (2) Dol-P is a product of Dol-P-Man and Dol-P-Glc dependent glycosyltransferases in the lumen of the ER, where seven Dol-P molecules are produced during each round of protein N-linked glycosylation. (3) Additional five Dol-P molecules are also formed in the lumen of ER as a result of GPI-anchor synthesis (three molecules per one GPI anchor synthesized) and protein C- and O-mannosylation (one for each reaction) (4) Dol-PP, a product of the OST catalysed N-linked glycosylation reaction, can be dephosphorylated to form Dol-P as well. Consequently, the bipartite localization of N-linked protein glycosylation, GPI-anchor biosynthesis and C- and O-mannosylation, results in a transfer of Dol-P from the cytoplasmic to the luminal side of the ER membrane. Luminal Dol-PP phosphatase, encoded by *CWH8*, has been described to dephosphorylate Dol-PP into Dol-P (van Berkel et al. 1999; Fernandez et al. 2001). The current models suggest that luminal Dol-P is then recycled and reused in glycosylation reactions. Since the phosphoryl group would prohibit free diffusion across the membrane, the rapid availability of Dol-P on the cytosolic side suggests active translocation across the membrane (McCloskey & Troy 1980; Sanyal & Menon 2010). The exact mechanism and proteins involved in the Dol-P recycling are to be further investigated.

2. Transfer of the LLO precursor to the polypeptide

Besides the use of Dol-PP as a carrier for LLO assembly, N-linked protein glycosylation is further characterized by the transfer of the fully assembled oligosaccharide from the Dol-PP carrier to the asparagine residues defined by the specific consensus sequence on nascent polypeptides in the ER lumen of eukaryotes or periplasm of bacteria and archaea. Oligosaccharyltransferase (OST) is the enzyme responsible for the catalysis of this glycosylation reaction.

2.1. Oligosaccharyltransferase (OST)

The central step of N-linked glycosylation is catalysed by the OST. In animals, plants and fungi the OST is a hetero-oligomeric complex composed of distinct membrane-bound subunits, involved in the *en bloc* transfer of a preassembled GlcNAc₂Man₉Glc₃ oligosaccharide to the asparagine side chain within the asparagine-X-serine/threonine consensus sequence (where X represents any amino acid except proline) of the nascent polypeptides as they enter the rough ER. The enzyme exist as a single subunit OST in certain unicellular eukaryotes and some archaeal and bacterial species (Wacker 2002; Kelleher and Gilmore 2006; Manthri et al. 2008; Nasab et al. 2008). Although the oligosaccharide structures transferred may differ, the formation of an N-glycosidic linkage between the amide nitrogen of the acceptor asparagine and C1 carbon of the first sugar residue on the LLO donor is evolutionary conserved (Bause & Legler 1981; Lizak et al. 2011).

2.1.1. *Saccharomyces cerevisiae* OST complex

OST has been most extensively studied in yeast. A combination of protein biochemistry and yeast genetics experiments has led to the identification of yeast OST as a complex of eight subunits encoded by *OST3/OST6*, *OST4*, *OST5*, *OST1*, *OST2*, *WBP1*, *SWP1* and *STT3*, where the last five are essential for survival (te Heesen et al. 1992; Stephan te Heesen et al. 1993; Kelleher & Gilmore 1994; Knauer & Lehle 1994; Zufferey et al. 1995; Chi et al. 1996; Karaoglu et al. 1997; Reiss, te Heesen, Gilmore, Zufferey & Aebi 1997; Spirig et al. 1997; Schwarz et al. 2005) (Figure 2). The complex exists in two isoforms, either containing Ost3p or Ost6p (Schwarz et al. 2005). Other organisms contain OSTs with distinct extent of structural complexity. The OST complex in mammalian cells encodes subunits homologous to those found in yeast: *N33/Tusc3* and *IAP3* (*OST3* and *OST6*), *DAD1* (*OST2*), *ribophorin I* (*OST1*), *OST48* (*WBP1*), *ribophorin II* (*SWP1*), where mammalian complex exists in two additional isoforms, containing either STT3A or STT3B (*STT3*) (Daniel J. Kelleher et al. 2003; Mohorko et al. 2011). Unicellular eukaryote *Cryptosporidium parvum* OST encodes for most of the subunits found in yeast except for *OST5* and

SWP1. Hetero-tetrameric OST complexes were described in *Trichomonas vaginalis*, *Entamoeba histolytica* and *Plasmodium falciparum* genomes where homologues encoding for *OST1*, *OST2*, *STT3* and *WBP1* were identified (Kelleher & Gilmore 2006).

Earlier studies demonstrated that yeast OST subunits have distinct interaction between each other and form three subcomplexes, the first subcomplex being described between Wbp1, Swp1 and Ost2 proteins, then Stt3p, Ost3/6p and Ost4p, and lastly between Ost1 and Ost5 proteins (Stephan te Heesen et al. 1993; Silberstein 1995; Karaoglu et al. 1997; Reiss, te Heesen, Gilmore, Zufferey & Aebi 1997). Recently, the work of Mueller and colleagues showed that the assembly of OST complex occurs in an ordered manner going through the formation of intermediate subcomplexes (Mueller et al. 2015). Taken together all the research, the order of the assembly of OST complex was proposed. It starts with the formation of the first subcomplex between Wbp1p, Swp1p and Ost2p. Similarly, Ost1p and Ost5p together with Stt3p form the second subcomplex. In the next step, the two subcomplexes interact and Ost4p subsequently binds to Stt3p and anchors Ost3/6p into the final active complex (Silberstein 1995; Karaoglu et al. 1997; Reiss, te Heesen, Gilmore, Zufferey & Aebi 1997; Spirig et al. 1997; Yan et al. 2003; Spirig et al. 2005; Mueller et al. 2015).

Figure 2. The oligosaccharyltransferase complex from yeast *Saccharomyces cerevisiae*.

The yeast OST complex is located in the ER lumen. It consists of eight subunits including Wbp1p, Ost2p, Swp1p, Ost1p, Ost5p, Stt3p, Ost4p and mutually exclusive Ost3p and Ost6p. OST catalyses the *en block* transfer of the GlcNAc₂Man₉Glc₃ LLO to the asparagine side chain within the N-X-S/T sequon of the polypeptide that has been translated and translocated into the ER by Sec61 translocon.

2.1.2. Function of distinct OST subunits

Stt3 subunit is the most conserved and is essential for the catalytic activity of the enzyme (Wacker 2002; Yan & Lennarz 2002; Daniel J. Kelleher et al. 2003; Nilsson et al. 2003). Homologues of Stt3p correspond to single subunit OSTs in unicellular eukaryotes (such as in kinetoplastids *Leishmania major* and *Trypanosoma brucei*), as well as archaeal and bacterial species (such as in *Campylobacter jejuni*) (Wacker 2002; Manthri et al. 2008; Nasab, Benjamin L. Schulz, et al. 2008). The overexpression of *L. major* Stt3p homologue in *S. cerevisiae* is sufficient to complement the deletion of *STT3* gene, even if they do not incorporate into the native complex (Nasab, Benjamin L. Schulz, et al. 2008; Hese et al. 2009). Therefore, cells with a non-functional yeast OST are viable in the presence of *LmStt3D* protein.

Some kinetoplastids, although having single subunit OSTs, encode several paralogues of *STT3*. Duplication and diversification of *STT3*, where the paralogues possess distinct preferences for LLO and polypeptide substrates, seems to represent an alternative approach to increase the number of protein substrates (Nasab, Benjamin L. Schulz, et al. 2008; Izquierdo et al. 2009; Schwarz & Aebi 2011). As mentioned above mammalian OST complex contains either Stt3A or Stt3B, where the two isoforms differ in their catalytic activity and selectivity for the LLO substrate (Daniel J. Kelleher et al. 2003). The *STT3A* isoform glycosylates substrate polypeptide chains cotranslationally, while *STT3B* isoform can posttranslationally glycosylate sites that were skipped by *STT3A* complexes. The presence of two OST complex isoforms with distinct properties and activities, similar to the presence of multiple paralogues of *STT3* in kinetoplastids, was suggested to increase glycosylation occupancy on different polypeptide substrates (Ruiz-Canada et al. 2009). It is worthy to mention that *S. cerevisiae*, as well as *Saccharomyces pombe* and *Caenorhabditis elegans*, express a single OST catalytic subunit that is more closely related to the *STT3B* isoform responsible for posttranslational glycosylation (Shrimal et al. 2013).

The addition of non-catalytic subunits is regarded as a mean to promote the catalytically active Stt3 protein to glycosylate a more diverse range of substrate proteins. Two best characterized OST subunits are Ost3 and Ost6, two proteins that define two OST complex isoforms in yeast (Schwarz et al. 2005). Glycosylation occupancy analysis on various glycosylation sites on cell wall proteins revealed that Ost3p and Ost6p facilitate efficient glycosylation in a site-specific manner (Schulz & Aebi 2009). Structural and biochemical characterization led to a model proposing that Ost3/6p form mixed disulphides with the protein substrates and thus prevent certain substrate polypeptides to oxidatively fold (Mohd Yusuf et al. 2013). In addition, noncovalent binding of polypeptides to Ost6p was also demonstrated (Jamaluddin et al. 2011). The model then proposes that different OST isoforms assist in

the binding of specific polypeptide substrates, increasing the time for efficient glycosylation of sites, which could otherwise be inaccessible due to protein folding prior to glycosylation (Schulz et al. 2009). Function of all other OST subunits is less clear. Structure of the smallest subunit, Ost4p, consisting only of a short membrane stalk has been solved and its sole function was proposed to mediate interaction between Stt3p and Ost3/6p (Gayen & Kang 2011; Dumax-Vorzet et al. 2013). The lack of large luminal domain in Ost5p might indicate its function mainly as structural component as well. For Ost1p, studies suggested that its mammalian homolog ribophorin I associated with ribosomes and facilitated delivery of some integral membrane proteins to the catalytic centre of OST (Yu et al. 1990; Wilson & High 2007; Wilson et al. 2008). Disruption of Wbp1p, Ost2p and Swp1p subunits caused destabilization of OST suggesting an important function in complex stabilisation although no further role has been proposed for these subunits (Mueller et al. 2015). A possible role of non-catalytic subunits could be to allow for a subtler regulation of the OST as additional subunits could facilitate glycosylation of different proteins or might regulate the selection of specific LLO substrates (Kelleher et al. 2007; Schulz et al. 2009). Moreover, additional subunits might provide a higher concentration of substrates at the catalytic centre. Lastly, additional subunits might mediate coupling of the OST to the translocon complex at ER membrane, resulting in more efficient glycosylation of sites that would otherwise be inaccessible. Previously published results indicate that ribophorin I, a human homologue of Ost1p, might be involved in the translocation process (Yu et al. 1990). All of these arguments would lead to one outcome, increased glycosylation on different polypeptide substrates.

2.1.3. N-linked protein glycosylation reaction

In order to catalyse the transfer reaction OST Stt3 subunit must recognize two distinct substrates: the LLO and the nascent polypeptide chains. The optimal LLO substrate of the yeast OST is a highly conserved $\text{GlcNAc}_2\text{Man}_9\text{Glc}_3$ oligosaccharide. Here, the presence of glucose moieties, in particular the terminal α -1,2-linked glucose, is crucial for the efficient transfer (Burda & Aebi 1998). Truncated LLO precursors can still be transferred, although less effectively causing protein hypoglycosylation (Verosteks et al. 1993). The length of the lipid carrier, dolichol, does not play an important role as shorter carriers were effectively utilized by the OST enzyme (Grabińska & Palamarczyk 2002). *In vitro* assays showed that the minimal oligosaccharide structure transferred by OST is Dol-PP-GlcNAc₂, while Dol-PP-GlcNAc₂Man₃ seems to be the minimal LLO structure that allows yeast cells to grow if the limiting translocation across the ER membrane is increased by Rft1p overexpression (Tai & Imperiali 2001; Helenius et al. 2002) (Figure 1). Thus, yeast cells with deletions of early *ALG* genes in the LLO biosynthetic pathway are not viable or display a severe growth phenotype (Albright & Robbins 1990; Jackson et al. 1993; Cipollo et al. 2001). Loss of luminal *ALG* enzymes results in protein

hypoglycosylation, but does not give a growth phenotype of corresponding strains. Interestingly, glycosyltransferase defects were more severe in respect of protein hypoglycosylation as compared to the loss of luminal mannosyltransferases, highlighting the importance of glucose residues in oligosaccharide recognition (Zacchi & BL. Schulz 2016). In summary, OST interacts with the LLO donor substrate in a highly specific way that favours the transfer of the mature LLO structure through the recognition of GlcNAc₂ core and the terminal α -1,2-linked glucose residue (Burda et al. 1999).

On the other hand, polypeptide substrates only seem to share the conserved N-X-T/S sequon. This strictly conserved property was found in eukaryotic and prokaryotic N-linked glycosylation (Marshall 1972; Wacker 2002; Abu-Qarn & Eichler 2007). The crystal structure of a bacterial single subunit OST, PglB, had provided the molecular basis for the understanding of N-linked protein glycosylation reaction (Lizak et al. 2011). The work of Lizak and colleagues revealed that the WWD motif (a diagnostic motif among Stt3 homologs) defines the OST sequon specificity, favouring a threonine or serine at +2 position. Earlier studies have shown that sequons containing threonine at the +2 position are glycosylated more efficiently compared to N-X-S sequons (Bause 1984; Breuer et al. 2001). The structure of PglB with bound acceptor peptide explained that this effect is due to stabilizing interaction of the PglB with the threonine residue, which is absent when serine is present at the +2 position. Furthermore, it revealed that the catalytic centre of the OST requires a polypeptide to bind in a loop, which almost completes a 180° turn, suggesting that the glycosylation sequons have to be located in flexible, surface exposed loops. This explained why proline residues are not present at the +1 position of the consensus sequon. The authors proposed a three-stage catalytic cycle for the single subunit OST glycosylation. Upon binding of the peptide substrate, the flexible external loop 5 (EL5) is engaged in restricting the movement of the peptide. This results in the formation of the catalytic centre and glycosylation. In the last stage, the EL5 is disengaged from the catalytic centre resulting in the release of glycosylated peptide (Lizak et al. 2011). Although the model proposed that the binding of acceptor peptide precedes that of the LLO, there is no experimental evidence to support this.

Earlier work has demonstrated that less than 65% of the overall glycosylation sequons are actually glycosylated (Petrescu et al. 2004). Hence, there are additional factors besides the consensus sequon that influence whether a certain glycosylation site is to be occupied or not. It has been shown that the nature of amino acids in the X position within the sequon, as well as in the regions surrounding the sequon may influence glycosylation (Shakin-Eshleman et al. 1996). The location of the sequon within the glycoprotein plays a role as well: if located near transmembrane regions or the carboxyl terminus the glycosylation efficiency may be decreased, although this effect may be protein specific (Nilsson & Von Heijne 2000). Protein secondary structure seems to be important as consensus sequons are required to be flexible in order to be accessible to the OST catalytic site. Such requirement explains

why in the eukaryotic systems N-glycans are attached preferentially to polypeptides before the protein folds into its native conformation. Although polypeptide substrates only seem to share the conserved N-X-T/S sequon, it is clear that this is not the sole determinant of whether a protein will be N-glycosylated. With the rest of the polypeptide being very diverse, OST needs to adopt a broad spectrum of interactions to successfully glycosylated multiple polypeptide substrates.

2. Functional roles of N-linked glycosylation

Once oligosaccharides have been transferred onto respective glycoproteins they partake diverse set of roles on, both, newly synthesized and mature glycoproteins. In the ER, glycan structures on newly synthesized glycoproteins contribute to quality control and influence protein folding (Aebi et al. 2010). N-linked glycans mediate transfer through the secretory pathway by providing signals for the intracellular transport and targeting (Ni et al. 2006). Once a glycoprotein has reached the final destination, N-glycans can provide different cell surface profiles or mediate interactions with extracellular environment, but can also be directly involved in the function of mature glycoproteins (Moremen et al. 2012). Lastly, the importance of N-linked glycans on proteins is underlined by congenital disorders of glycosylation (CDGs) in humans, a series of diseases correlated with defects in the N-linked glycosylation pathway (Hennet 2012).

2.1. ER quality control and unfolded protein response

N-linked glycans effect the properties of the newly synthesized glycoproteins where the presence of hydrophilic oligosaccharides facilitates protein folding, as well as the overall stability of glycoproteins (Hanson et al. 2009; Braakman & Hebert 2013).

N-linked glycans have a role in the ER quality control (ERQC), where the function of the ERQC machinery is to allow only properly folded proteins to reach their final destinations through the secretory pathway. The ERQC mechanism relies on two major ER resident chaperone systems: the classical chaperones and the carbohydrate-binding chaperones, both being able to promote the efficient folding, but also have the ability to evaluate the conformational state of their substrates (Aebi et al. 2010; Braakman & Hebert 2013). The classical chaperones, belonging to the ER primary quality control mechanisms that apply to all proteins regardless of their glycosylation status, are capable of identifying their substrates based on the presence of exposed hydrophobic regions normally buried in the native proteins (Ellgaard & Helenius 2003). The second chaperone system consists of the

carbohydrate-binding chaperones that are specialized for recognition of specific oligosaccharide structures on the glycoproteins. Modifications of the N-linked glycan structure occurring inside the ER, after the oligosaccharide has been transferred, help the quality control system to distinguish between folding intermediates, fully folded or misfolded proteins (Aebi et al. 2010). After the OST transfers the $\text{GlcNAc}_2\text{Man}_9\text{Glc}_3$ to the nascent polypeptide, glucosidase I and II sequentially remove the glucose residues. The N-linked glycan is then re-glucosylated by an UDP-Glc:glycoprotein glycosyltransferase (UGT1) that adds α -1,3-linked glucose residue to glycan a branch. UGT1 is a sensor of glycoprotein conformation as it is specific for unglucosylated glycans on unfolded but not native polypeptides. Monoglucosylated N-linked glycan is specifically recognised by the lectin chaperones calnexin and calreticulin that help the polypeptide to fold correctly. It has been shown that both lectins form a complex with ERp57, a thiol-disulphide oxidoreductase known to form native disulphide bonds in folding polypeptides. Glucosidase II is then responsible for dissociation of glycoprotein substrate from calnexin or calreticulin by removing the terminal glucose. If the glycoprotein still has not reached its native conformation it will be re-glucosylated by UGT1 and the whole cycle starts again (Ellgaard & Helenius 2003; Aebi et al. 2010).

Ultimately, if a polypeptide is not able to fully fold in appropriate time, even after cycles of glucosylation and de-glucosylation, the N-linked glycan structure will target the respective glycoprotein at the ER-associated degradation pathway (ERAD) (Thibault & Ng 2012; Christianson & Ye 2014). The unfolded glycoprotein is diverted for the degradation upon the action of ER resident α -1,2 mannosidase I, encoded by *MNS1* in yeast, that trims the terminal b branch mannose from the N-linked glycan. The glycoprotein is still able to properly fold and additional chaperons like Pdi1p and Kar2p assist in this process. At this stage, if the folding is successful, the native glycoprotein will exit the ER carrying $\text{GlcNAc}_2\text{Man}_8$ N-linked glycan. On contrary, the trimming of the b branch mannose leads to an association with ER degradation enhancing 1,2 mannosidase like protein (EDE1), encoded by *HTM1* in yeast, that removes the terminal c branch mannose and exposes the terminal α -1,6-linked mannose residue that serves as the N-glycan degradation signal. Htm1p was found in complex with Pdi1p, here serving to identify unfolded substrates for Htm1p (Gauss et al. 2011). The N-linked glycan with the exposed α -1,6-linked mannose is ligand for yeast ERAD lectin Yos9p. In combination with Hrd3p that detects misfolded stretches on the glycoprotein, Yos9p recognition will target the protein for ubiquitination by Hrd1p, followed by degradation (Quan et al. 2008; Zattas & Hochstrasser 2015).

Alternatively, a second mean of coping with unfolded proteins in the ER is the unfolded protein response (UPR) machinery. In the UPR, the accumulation of unfolded ER proteins leads to transcriptional induction of UPR target genes (Chapman et al. 1998). Many of the UPR target genes have been identified by now, where most encode ER-resident chaperones that bind to misfolded

proteins, prevent aggregation, and promote folding. In addition, components of the phospholipid and different glycosylation biosynthetic pathways are targets as well, together with proteins involved in vesicular transport and ERAD (Travers et al. 2000). It is believed that activation of N-linked glycosylation enzymes would assist in the folding of proteins that require carbohydrate modification to attain their proper conformation. Interestingly, UPR induction in mammalian cells was shown to accelerate synthesis of the dolichol-oligosaccharides employed in N-linked glycosylation (Doerrler & Lehrman 1999). Regulation of gene expression by the UPR allows the cell to cope with folding stress and adjust the capacity of protein folding in the ER according to the need, although how N-linked glycosylation components are directly involved in this regulation needs to be further investigated.

2.3. Congenital disorders of glycosylation

Many proteins are modified by glycans that can be crucial for protein function, localization, transport and/or protein stability (Larkin & Imperiali 2011). The essentiality of the correct assembly of the N-linked glycan and its attachment to different protein substrates was further highlighted with the discovery of CDG syndromes in humans. Although clinically heterogeneous, most types of CDGs are associated with neurological impairments ranging from severe psychomotor retardation to moderate intellectual disabilities, and in worst cases, to infantile lethality (Haeuptle & Hennet 2009). CDG patients were identified using serum transferrin isoelectric focusing, although in the last years, sequencing techniques are commonly used. By now, CDG patients with mutations in all genes involved in LLO biosynthesis (except *ALG10*) were described, where some of these genes were associated with congenital myasthenic syndromes or impaired neuromuscular transmission as well (Freeze 2006; Haeuptle & Hennet 2009; Timal et al. 2012; Cossins et al. 2013). CDGs have also been identified for mutations affecting different OST subunits and subsequent modification steps of the N-glycans (Hennet 2012). Insects and plants are also affected by defects in the N-linked glycosylation pathway which can lead to developmental alterations and hypersensitivity to stress conditions (Haecker et al. 2008; Pattison & Amtmann 2009; Farid et al. 2011; Shaik et al. 2011). Further identification and investigation of CDGs and similar diseases might improve our understanding of glycosylation pathways and their complex regulation.

3. Analytical tools for the analysis of N-linked glycosylation

Considering the importance of N-linked glycosylation discussed above, it is not surprising that this process has been extensively studied over the years. This section will be discussing the analytical tools used to examine OST complex stability and the enzyme activity in respect of glycosylation occupancy, a term describing the presence or absence of glycans on glycoprotein substrates.

3.1. Genetic and biochemical analysis of N-linked protein glycosylation

Although the genetic analysis of N-linked glycosylation pathway has been performed in many model organisms, including bacteria, yeast and mammalian cells, the ease of genetic manipulation makes the yeast *Saccharomyces cerevisiae* the best eukaryotic model organisms for the analysis of this pathway (Frazer & O'Keefe 2007). The facility of transformation and homologous recombination, including the possibility of complementation with different auxotrophy marker genes, have enabled the isolation of many mutants that helped understand the function of the pathway as well as the distinct roles of OST subunits. Yeast genetic techniques have enabled the identification of all loci required in the assembly of LLO. In brief, *ALG1*, *ALG2* and *ALG11* loci were cloned by complementation of the temperature-sensitive phenotype of the corresponding mutants; *ALG13* and *ALG14* were identified based on *in silico* search; *ALG3*, *ALG9*, *ALG12*, *ALG6*, *ALG8* and *ALG10* were isolated through a synthetic lethal screen or through sensitivity or resistance to different toxins, or mannose-suicide selection (Burda & Aebi 1999; Breitling & Aebi 2013). Furthermore, isolation of OST mutants and high copy number suppression of the temperature-sensitive phenotype of these mutants led to identification of all OST complex subunits. Shortly, *SWP1* and *OST2* loci were isolated as high copy number suppressors of *wbp1* mutants, *OST5* was a suppressor of *ost1* mutant and *Ost3p* overexpression suppressed the *ost4* deletion phenotype while *OST3* and *OST4* are high copy number suppressors of *stt3* mutants (Kelleher & Gilmore 2006). As majority of genes involved in N-linked glycosylation pathway have been identified, genetic manipulation of the genes involved facilitates further investigation of the pathway.

Biochemical methods, such as co-immunoprecipitation and chemical cross-linking, have been used to investigate the interaction between OST subunits as well as the role of WWYDG motif of *Stt3p* in peptide recognition (Yan & Lennarz 2002; Nilsson et al. 2003; Yan et al. 2003). Chromatographic and immunoaffinity methods have been used to purify OST from various organisms later used for *in vitro* activity assays (Kumar et al. 1994). Earlier, OST activity assays were often conducted using radiolabelled LLOs and isotopically labelled or biotinylated peptides (Xu & Coward 1997; Srinivasan & Coward 2002). Current assays use fluorophore labelled synthetic peptides that are electrophoretically separated and detected by fluorescence gel imaging, offering an easier, faster and less hazardous

approach compared to the previous one (Kohda et al. 2007; Gerber et al. 2013; Lizak et al. 2013). Most common way of OST *in vivo* activity investigation uses Western blot analysis followed by immunodetection of specific glycoproteins where the extent of protein hypoglycosylation is evident from a ladder like appearance of faster moving, hypoglycosylated protein species. Broadly used model glycoprotein in glycosylation occupancy analysis is a vacuolar protease CPY that harbours four glycosylation sites. Although quite swift and easy, this type of analysis is low throughput since only a few glycoproteins can be monitored per experiment. Recent approaches use mass spectrometry offering precise, reproducible and high throughput workflows for the analysis of glycosylation occupancy. The following pages will be focusing on different mass spectrometry techniques used for the investigation of N-linked protein glycosylation.

3.2. Mass spectrometry analysis of N-linked protein glycosylation

Mass spectrometry (MS) is an analytical method that allows identification and quantification of molecules based on their mass and charge. Every mass spectrometer includes an ion source, a mass analyser and a detector. For each part of the instrument, different types of devices are available and their combination allows a number of different applications. In proteomics, mass spectrometry is used either to identify the overall protein content of a sample using shotgun proteomics, or to focus on quantification of specific analytes using targeted proteomics. The two targeted techniques discussed below are Selected Reaction Monitoring (SRM) MS and Parallel Reaction Monitoring (PRM) MS. An alternative technique that combines shotgun with targeted data analysis is Sequential Window Acquisition of all Theoretical mass spectra (SWATH) MS (Figure 3). In all cases a standard proteomics workflow includes: (1) protein extraction, (2) digestion into peptides, (3) separation using liquid chromatography (LC), (4) ionization before entering the mass analyser where ionized peptides, also called precursor ions, are resolved according to their mass-to-charge (m/z) ratio and MS^1 (or MS) spectrum is recorded, (5) selection of particular precursor ions and their fragmentation in a process termed collision-induced dissociation (CID) and (6) record of fragment ions of a single peptide in MS^2 (or MS/MS) spectrum (Figure 3) (Steen & Mann 2004).

Glycoproteomics, the global analysis of glycoproteins, is a field of proteomics for the systematic identification and quantification of glycoproteins in complex biological samples. While glycomics analysis focuses on characterization of the glycan structure attached to proteins, the emerging techniques in glycoproteomics are focused on the identification of protein glycosylation sites and quantification of glycosylation site occupancy.

3.2.1. Supporting techniques for the analysis of glycoproteins by MS

Although ubiquitous, the glycoproteome is overshadowed by the complicated cellular environment, due to the relative low abundance and low MS properties of glycosylated peptides additional steps are usually required for the analysis of glycoproteins by MS. In order to reduce sample complexity a basic workflow was established for the analysis of glycoproteins by MS following adequate sample preparation often including the cell fractionation, glycoprotein or glycopeptide enrichment and trimming of the glycan moiety.

Many enrichment methods on glycoprotein and/or glycopeptide level have been developed that can be divided into affinity approach and chemical approach (Pasing et al. 2012). The affinity approach relies on the interaction of glycans and stationary phase such as lectin affinity chromatography, titanium dioxide (TiO₂) affinity chromatography and hydrophilic interaction liquid chromatography (HILIC). The chemical approach is based on immobilization of glycoproteins or glycopeptides relying on the chemical interaction of glycans and specific functional groups, such as hydrazine chemistry, reductive amination chemistry and boronic acid chemistry. Probably the most renowned method for glycoprotein or glycopeptide enrichment is lectin affinity chromatography with the advantage of broad spectrum of available specificities. Commonly used lectins are: wheat germ agglutinin (WGA) prefers dimers and trimers of GlcNAc and sialic acid-bearing glycans; concanavalin A (ConA) binds core α -mannose residues and is therefore preferentially used for the enrichment of N-glycopeptides; and galactosyl(-1,3)-GalNAc and O-glycoprotein specific jacalin (JAC) (Baenzigers 1979; Chatterjee et al. 1985; Debray et al. 2005). Despite the advantage of their specificity, the use of lectins has drawbacks, such as secondary specificity and low binding efficiency in protein mixtures (Lee et al. 2010). A broad range of glycoproteins and glycopeptides can be enriched by solid-phase extraction method used in hydrazine chemistry (Zhang et al. 2003). Although the method has been successfully used to investigate many complex biological samples, it requires careful optimization and extensive preparation. Recently, the application of HILIC has been used in glycoproteomics. This non-modifying technique relies on the hydrophilic interaction between the glycan moiety and the stationary phase separating the glycopeptides from the rest of the non-glycosylated peptides that are washed out with an organic solvent. The newest strategy combines HILIC with zwitterionic materials (ZIC-HILIC) creating a column of high ionic strength for polar interaction with glycans. This strategy has been successfully used for the enrichment and identification of glycopeptides in different studies (Hägglund et al. 2004; Neue et al. 2011).

After enrichment of the glycopeptides, most workflows proceed with the trimming of the glycan moiety before MS analysis. Two most commonly enzymes used are N-glycosidase F (PNGaseF) and endo- β -N-acetylglucosaminidase (EndoH). PNGase F cleaves all N-glycans between the reducing end

GlcNAc and the asparagine residue, except those carrying an α -1,3-linked fucose attached to GlcNAc, as observed in plants and some insects (Tarentino et al. 1985; Tretter et al. 1991). Glycan digestion with PNGase F results in a deamination of asparagine to aspartic acid at the former glycosylation site. The resulting mass shift of 0.98 Da can be detected by MS and can be used as an indirect assignment of former glycosylation sites (Zhang et al. 2003). However, deaminations can occur naturally within a cell or during sample preparation resulting in false positive results. The use of ^{18}O -water during PNGaseF digestion helps to rule out natural deamination and increases mass difference, although it does not exclude the possibility of spontaneous deamination during sample preparation (Beck et al. 2011). The use of Endo H, which cleaves between the two first GlcNAc residues of high-mannose and some hybrid oligosaccharides of N-linked glycoproteins leaving a remnant GlcNAc residue, unambiguously marks the glycosylation site during MS analysis (Tarentino et al. 1974; Hägglund et al. 2004). However, a neutral loss of the labile GlcNAc can occur during the fragmentation of the peptide in the mass spectrometer, although this can be avoided using appropriate fragmentation technique (such as electron-transfer dissociation (ETD) or electron-capture dissociation (ECD)) (Wiesner et al. 2008).

In order to facilitate and improve quantification of complex biological samples label-based approaches have been developed where the ratios of mass spectrometry intensities between the "light" and "heavy" samples are calculated. Various approaches include metabolic incorporation, stable isobaric or isotopic labelling using chemical reactions, use of spiked synthetic peptide standards and enzymatic reactions using ^{18}O labelling mentioned above (Bantscheff et al. 2007). Metabolic incorporation or Stable Isotope Labelling by Amino acids in Cell culture (SILAC) is a simple, straightforward and most accurate labelling approach where non-radioactive, stable isotope-containing amino acids are incorporated *in vivo* into proteins (Ong 2002). It involves growing the cells in growth medium where natural amino acids are replaced by "heavy" amino acids, usually arginine and lysine, that are then being incorporated into newly synthesized proteins. This way the label is introduced in the earliest possible point and hence it excludes all sources of quantification error introduced by biochemical and MS procedures. However, the approach is costly and sometimes not feasible for the metabolic labelling in higher eukaryotes (Ong & Mann 2006).

In the following part, we will be discussing current existing MS technologies utilized for the characterization and identification of N-glycoproteins as well as for the understanding of N-linked glycosylation pathway.

3.2.2. Shotgun MS for the identification of glycoproteins

In the shotgun proteomics, all precursor ions are detected, resulting in MS¹ spectra acquired over the whole LC gradient, and the most intense ions present in MS¹ spectra will sequentially be isolated, fragmented and recorded in MS² spectrum. This results in the "fingerprint" of each peptide's fragmentation mass spectrum. To identify the peptides and proteins, the MS² spectra are searched against a database (with commercially available software such as Mascot or Sequest) containing the theoretical spectra of the whole proteome of interest, enabling the identification of thousands of proteins in a single experiment, while requiring only minimal prior knowledge about the sample (Wu & MacCoss 2002).

Shotgun proteomics have proved to be a powerful tool to investigate the extent of glycoproteome in various organisms. Using shotgun proteomics, Zielinska and colleagues have identified 516 glycosylation sites in yeast *Saccharomyces cerevisiae*, 425 in the fission yeast *Schizosaccharomyces pombe*, 1794 in *Caenorahbditis elegans*, 2186 in plant *Arabidopsis italiana*, 2229 in fly *Drosophila melanogaster*, 2254 in zebrafish *Danio rerio* and 6367 in four mouse tissues (Zielinska et al. 2010; Dorota F. Zielinska et al. 2012). Furthermore, shotgun method was used for the identification and semi-quantification of salivary N-glycoproteins (Xu et al. 2014). Although relevant when it comes to identification of distinct glycoproteins, due to the selection of only the most intense ions, shotgun proteomics approach offers low or failed identification of low abundant proteins, making the quantification of those proteins challenging. For the reproducible and sensitive quantification of proteins, other proteomics approaches have been successfully used.

3.2.3. SWATH MS for the analysis of N-linked glycosylation occupancy

SWATH MS is a recently developed method where all precursor ions within a defined mass windows or swaths, covering the entire m/z range are sent for fragmentation and full MS² spectra are then obtained, allowing for higher quantification accuracy and precision compared to shotgun (Gillet et al. 2012). The spectra are then analysed in a targeted way using sophisticated software, such as Skyline, PeakView or OpenSWATH, to group the fragment ions based on their retention time and the precursor ion mass window (MacLean et al. 2010; Röst et al. 2014).

SWATH MS method has been used for automated measurement of site-specific glycosylation in yeast cell wall preparations, human saliva and in human plasma (Liu et al. 2013; Xu et al. 2015). Additionally, using SWATH MS Zacchi and Schulz have studied how mutations in N-linked glycosylation pathway lead to changes in glycosylation occupancy as well as in the structure of glycans at a specific site in yeast

cell wall glycoproteins (Zacchi & BL. Schulz 2016). They have shown that mutations in earlier mannosylation or glucosylation steps of LLO biosynthesis had stronger phenotypes, although glucosylation defects were in general more severe as compared to mannosylation defects. Furthermore, the study provided insight into the role of the non-essential OST subunits. Loss of non-essential subunits affected glycosylation in site-specific manner, where the deletion of *OST3* led to most severe hypoglycosylation. The deletion in *OST5* had a less severe effect as compared to loss of Ost3p, while *OST6* deletion had a minor hypoglycosylation phenotype (Zacchi & BL. Schulz 2016).

Figure 3. Schematic representation of different MS techniques.

From the proteins of interest defined in the context of a biological question, a set of peptides are generated that can be analysed by various MS analyses. In SWATH, all peptide ions within a defined mass windows or swaths are sent for fragmentation and all possible fragment ion transitions are analysed. The obtained spectra are then analysed in a targeted way. Q1 refers to the first mass-resolving quadrupole while the second mass analyser is commonly a time-of-flight (TOF) mass analyser. In SRM, only selected peptide ions are sent for fragmentation and only selected fragment ion transitions are serially monitored one at a time. Q1 and Q3 refer to the first and third mass-resolving quadrupoles. In PRM, only selected peptide ions are sent for fragmentation but all possible fragment ion transitions are analysed in one high resolution and high mass accuracy mass analysis. Q1 refers to the first mass-resolving quadrupole while the second mass analyser is commonly an Orbitrap.

3.2.4. SRM MS for the analysis of OST complex stability

Although SWATH experiments are well suited for quantification studies, the sensitivity and selectivity of this approach is not good enough for the analysis of low abundant compounds in complex samples. Therefore, targeted methods were developed that involve the selection of predetermined set of peptide ions of interest and their respective fragment ions prior to MS analysis. SRM, often called Multiple Reaction Monitoring (MRM), is a common targeted MS technique where predefined pairs of peptide/fragment ions (called transitions) of interest are monitored, resulting in increased sensitivity of measurements (Picotti et al. 2009). SRM assays require prior knowledge about the peptide ion m/z , elution time and characteristic high-intensity fragment ions. This information is entered into the instrument software as a transition list. Sophisticated software (such as Skyline) are used for the data analysis where the peptide ion and a specific fragment ion are grouped into a transition and all transitions are assembled into a peak (MacLean et al. 2010). Although SRM offers precise quantification over a wide dynamic range, the low resolution of both mass analysers and the number of targeted peptides can result in low selectivity and limit the measurement specificity.

Some studies describe the use of SRM MS for the quantification of glycosylation occupancy focused on the investigation of a small number of glycoproteins in human samples (Kim et al. 2012; Hong et al. 2013). Using yeast genetic methods to individually affect OST subunits with SILAC based SRM approach, Mueller and colleagues have analysed OST subunit protein degradation rates and relative amounts in steady state (Mueller et al. 2015). They showed that deleting essential subunits destabilized the OST complex while the overexpression of individual subunits resulted in degradation of the excess subunit without perturbing the complex. Using relative quantification of subunit levels in steady state, they have deduced the order of assembly of OST complex subunits discussed earlier.

3.2.5. PRM MS for the analysis of N-linked glycosylation occupancy

PRM is a novel targeted MS technique implemented on high resolution/accurate mass (HRAM) instruments resulting in improved sensitivity and selectivity allowing for reliable quantification of low abundant proteins (Gallien et al. 2012; Peterson et al. 2012). During PRM measurement the peptide precursor ion is selected in the first mass analyser, fragmented in the second and unlike SRM, all generated fragments are monitored in parallel with a full scan mass spectrometer. The time spent to analyse the ions in the last mass analyser, called transient time, is determined by the predefined operating resolving power. Similar to SRM, the data processing is done by sophisticated software (such as Skyline) although the post-acquisition analysis of PRM assay is more flexible and selective. The general advantages of PRM are higher specificity, sensitivity and no prior knowledge of the target transitions is required hence less time is needed for assay development.

We applied PRM MS technique for the quantification of N-linked glycosylation occupancy on numerous glycoproteins from membrane preparations of yeast *Saccharomyces cerevisiae* (see Chapter 2; Poljak et al. unpublished).

4. Concluding Remarks

Asparagine-linked protein glycosylation in the lumen of the endoplasmic reticulum is a ubiquitous, essential and evolutionary highly conserved protein modification, important for protein folding and stability as well as for distinct cellular functions. The pathway is characterized by the use of Dol-PP as a carrier for LLO assembly, a bipartite localization and the transfer of the completely assembled GlcNAc₂Man₉Glc₃ oligosaccharide from the Dol-PP carrier to the asparagine residues defined by the specific consensus N-X-S/T sequence. The last and key step of the pathway is catalyzed by the hetero-oligomeric OST complex in *Saccharomyces cerevisiae*. Five of OST subunits in yeast, Wbp1, Swp1, Ost2, Ost1, and Stt3, are essential for viability of the cell, whereas Ost4, Ost5, Ost3, and Ost6 are not essential but are required for maximal OST activity. The essential Stt3p is the catalytic subunit of OST and is responsible for the transfer of the oligosaccharide. There are organisms that contain only some of the OST subunits or only encode *STT3* homologues that serve as single subunits OST, but in all of these organisms, the basic mechanisms of N-linked glycosylation are conserved. Besides their importance for complex stability, the specific function of the non-catalytic subunits is largely unknown. The work described in the following chapters is trying to illuminate the mechanism of action of the multi-subunit OST complex from yeast *Saccharomyces cerevisiae* as well as of the single subunit *STT3* paralogues from *Trypanosoma brucei*.

Construction of strains

Preparation of samples for mass spectrometry.

PRM and shotgun MS measurements.

Data analysis.

Writing the manuscript.

Summary

Asparagine-linked glycosylation is a common posttranslational protein modification regulating the structure, stability and function of many proteins. N-linked glycosylation machinery involves enzymes responsible for the assembly of the lipid-linked oligosaccharide (LLO), which is then transferred to the asparagine residues on the polypeptides by the enzyme oligosaccharyltransferase (OST). A major goal in the study of protein glycosylation is the establishment of quantitative methods for the analysis of site-specific extent of glycosylation. Here, we developed a sensitive approach to examine glycosylation site occupancy in *Saccharomyces cerevisiae* by coupling stable isotope labelling (SILAC) approach to parallel reaction monitoring (PRM) mass spectrometry (MS). Combined with genetic tools, this analysis allowed identification of novel glycosylation sites dependent on the Ost3p and Ost6p regulatory subunits of OST. Furthermore, we applied this approach to show that the glycosylation efficiency of the OST is influenced by the preceding binding of the LLO donor substrate and the folding speed of protein substrates. We also demonstrated the utility of our approach for the quantitative assessment of additional networks directly or indirectly connected to protein glycosylation.

Introduction

Glycosylation is a fundamental part of life whose impact and intricacy increase with the complexity of the organism (Dorota F Zielinska et al. 2012). Glycans affect protein folding, stability and degradation, they mediate interactions of all cells and regulate essential biological, chemical and physical processes (Varki 1993). Asparagine linked N-glycosylation is an essential modification of proteins conserved between eukaryotes, archaea and some bacteria (Szymanski & Wren 2005). In eukaryotes, the reaction is catalysed by oligosaccharyltransferase (OST) in the lumen of the endoplasmic reticulum (ER) (Kelleher & Gilmore 2006). Upon arrival of protein substrate to the lumen of the ER, the preassembled oligosaccharide is transferred, co-translationally or post-translationally, en bloc from the lipid carrier dolichol pyrophosphate (Dol-PP) to asparagines in selected glycosylation sequons (N-X-S/T; X≠P) (Kelleher & Gilmore 2006; Kelleher et al. 2007). After the oligosaccharide has been transferred, the N-linked glycan structure influences protein folding and helps ER quality control (ERQC) machinery to distinguish between folding intermediates, where only properly folded proteins are allowed to reach their final destinations through the secretory pathway (Aebi et al. 2010). Eventually if a polypeptide is not able to reach its native conformation, the misfolded glycoprotein will be recycled in the ER-associated degradation (ERAD) pathway (Zattas & Hochstrasser 2015). Alternatively, accumulation of unfolded proteins in the ER will lead to ER stress and activation of an unfolded protein response (UPR) pathway, where transcriptional induction of UPR target genes allows the cell to adjust the capacity of protein folding in the ER (Chapman et al. 1998; Travers et al. 2000). Many proteins are modified by glycans that can be crucial for protein folding, stability, transport, localization and/or function, hence the study of correct assembly of the N-linked glycans and its attachment to different protein substrates has been of great interest since (Larkin & Imperiali 2011).

In yeast, the N-linked glycosylation pathway starts with the assembly of the $\text{Glc}_3\text{Man}_9\text{GlcNAc}_2$ lipid-linked oligosaccharide (LLO) on a Dol-PP carrier on the ER membrane (Helenius & Aebi 2004; Breitling & Aebi 2013). The LLO is synthesized in a defined, stepwise manner by a series of enzymes belonging to the ALG (Asparagine-Linked Glycosylation) family (Burda & Aebi 1999). The process starts on the cytoplasmic side of the ER membrane, where $\text{Man}_5\text{GlcNAc}_2$ heptasaccharide is assembled on the Dol-PP by sequential action of the Alg7/Alg13/Alg14 and the Alg1/Alg2/Alg11 enzyme complexes (X.-D. Gao et al. 2004; Lu et al. 2012). These glycosyltransferases use nucleotide-activated sugars as donors. The LLO is then flipped onto the luminal side of the ER by a process requiring Rft1p (Helenius et al. 2002). The LLO is further elongated by the action of Alg3p, Alg9p, Alg12p, and again Alg9p that add four additional mannosyl residues. The LLO structure is completed by the action of three glucosyltransferases Alg6, Alg8 and Alg10. Unlike the cytoplasmic glycosyltransferases, luminal ALG enzymes utilize Dol-P-bound sugars as donors and have a high LLO substrate specificity that ensures

an assembly of an optimal OST LLO substrate that exposes the terminal α -1,2-linked glucose (Lairson et al. 2008). As a result, Alg12p will only be able to add the α -1,6-linked Man residue to the α -1,2-linked Man, once α -1,2-linked Man has been attached by Alg9p (Jakob et al. 1998). Due to sequential nature of LLO biosynthesis, deficiencies in ALG enzymes result in accumulation of LLO intermediates. Truncated LLO structures will still be transferred by the OST though will a lower efficiency, resulting in the appearance of hypoglycosylated protein substrates (Karaoglu et al. 2001).

In higher eukaryotes, OST is a multiprotein complex consisting of different subunits (Stt3p, Ost1p, Ost5p, Wbp1p, Ost2p, Swp1p, Ost3p/Ost6p and Ost4p in yeast *S. cerevisiae*). Some protozoan, archaeal, and bacterial species have a single protein OST, homologous with Stt3p, the catalytic protein subunit of the eukaryotic OST (Kelleher & Gilmore 2006). From the phylogenetic analysis yeast STT3 is proposed to be a B type STT3 that is not associated with the translocon (Ruiz-Canada et al. 2009). As consensus sequons are required to be flexible in order to be accessible to the OST catalytic site, there is a competition between folding and glycosylation (Lizak et al. 2011). Consequently, OST has evolved ways of competing with protein folding. In yeast, the presence of either Ost3p or Ost6p results in two alternative OST complexes (Spirig et al. 2005). Both subunits have thioredoxin-like ER luminal domains that transiently capture stretches of OST protein substrates in the ER through noncovalent or mixed disulfide bonds (Fetrow et al. 2001; Jamaluddin et al. 2011; Mohd Yusuf et al. 2013). The proposed role of these subunits is to increase the efficiency at particular glycosylation sites by guiding the catalytic site of OST to nearby sequons and inhibiting local polypeptide folding (Schulz et al. 2009; Jamaluddin et al. 2014). The roles of the additional subunits in the eukaryotic OST are mostly unknown but may be necessary for directing the glycosylation toward particular protein substrates and glycans.

Mass spectrometry (MS) has become the method of choice for the identification and quantification of N-linked glycoproteins (Zhang et al. 2003; Lazar et al. 2013; Liu et al. 2013; Parker et al. 2013; Song et al. 2013; Pan 2014; Xu et al. 2015; Yeo et al. 2016; Zacchi & Schulz 2016). MS assays rely on the elution time and precursor mass of the modified peptides, as well as the mass-to-charge ratio and relative intensity of specific fragment ions that indicate the sequence position of modified asparagine residues. Several MS techniques for measuring N-linked glycosylation site occupancy in yeast have been described utilizing different modes of operation for targeted glyco-peptide analysis, such as SRM (Selected Reaction Monitoring), SWAT (Sequential Window Acquisition of Targeted fragment ions) and data-independent techniques, such as SWATH (Sequential Window Acquisition of all Theoretical fragment ion spectra) (Xu et al. 2015; Zacchi & Schulz 2016; Yeo et al. 2016). These techniques have used isolation of the glycoprotein rich cell wall fraction for sample simplification. However, cell wall fractionation can introduce analytical bias as proteins that are inefficiently glycosylated in the ER tend to fold incorrectly and are prevented from trafficking out of the ER by ERQC mechanism (Aebi et al.

2010; Zattas & Hochstrasser 2015). In this paper, we describe a novel method for the identification and relative quantification of N-linked glycosylation occupancy and protein abundance of yeast membrane and luminal proteins using SILAC (Stable Isotope Labelling by Amino acids in Cell culture) strategy combined with PRM (Parallel Reaction Monitoring) based MS method. The PRM technique is currently the most powerful mode of targeted proteomics analyses for quantitative measurements in biological samples and this is the first time it is being exploited for quantitative analysis of N-linked glycosylation. We took advantage of the latest generation HRAM (High Resolution Accurate Mass) analysers usually utilized in PRM analyses, which dramatically increase the selectivity of measurements by reducing the signal interference in complex samples, and the accurate mass measurement capability, which enhances the confidence in the assignment of the fragment ions. Both qualities improve the analysis of low abundance peptides and enable us to successfully detect N-GlcNAc peptides, resulting from endoglycosidase H glycan release used in the sample preparation, without a prior glycoprotein and/or glyco-peptide enrichment. Furthermore, we used the SILAC strategy based on stable isotopes being incorporated into cellular proteome by *in vivo* metabolic labelling and mixing at the cellular level to achieve higher quantitative accuracy, thus minimizing handling bias (Ong 2002; Ong & Mann 2006). Heavy isotopes of arginine and lysine amino acids are added to yeast cultures and using tryptic digestion, which results in peptides containing either one lysine or one arginine residue, ratios of each peptide could be determined accurately in the SILAC samples. We decided to perform our analysis on yeast microsomal fractions, thus enriching for membrane and luminal proteins as those are the most abundant glycoproteins in yeast cells and by doing so are able to monitor glycosylation occupancy of all OST glycoproteins and several glycoproteins whose structures have been solved. This type of analysis provides us with quantitative results of increased precision and allows us to monitor an extended list of novel glycosylation sites, as compared to SRM, SWATH, SWAT or other proteomics approaches utilized before (Schulz & Aeby 2009; Xu et al. 2015; Zacchi & BL Schulz 2016; Yeo et al. 2016). We implemented newly developed SILAC PRM MS method, together with yeast genetic approaches, to analyse glycosylation occupancy as well as cellular abundance, since these have profound physiological effects and may fluctuate independently, of many glycoproteins in multiple yeast mutants. By simultaneous analysis of protein levels we are able to study the effect of glycosylation on protein folding and UPR activation. Finally, we exploited the ease of developing a directed PRM assay to quantify protein levels of a majority of proteins involved in mevalonate and ergosterol pathway, which enabled us to investigate the intricate connection between dolichol and ergosterol biosynthetic pathways.

Results

SILAC based PRM MS for quantitative profiling of N-glycoproteins in yeast

To design targeted MS assays for site-specific quantification of N-linked glycosylation site occupancy in yeast *Saccharomyces cerevisiae*, we focused on glycoproteins originating from microsomal fractions (Mueller et al. 2015). A schematic overview of our assay development and workflow is presented in Figure 1. In a discovery phase, glyco-peptides originating from microsomal fractions were enriched after proteinase digestion (Figure 1). Glycoproteins originating from microsomal fractions were digested sequentially with LysC and trypsin proteinase. The use of both proteinases, compared to the use of trypsin proteinase alone, has been shown to result in higher yields, higher reproducibility and more accurate quantification (McDonald et al. 2002). We enriched for glyco-peptides by solid-phase extraction (SPE) using zwitterionic hydrophilic interaction chromatography (ZIC-HILIC) to ensure high coverage of hydrophilic N-linked glyco-peptides as described previously (Neue et al. 2011). Glycans were released with endoglycosidase H leaving previously glycosylated asparagine residues tagged with a single GlcNAc residue and identified by shotgun-MS. The use of Endo H offers an additional advantage over other analyses that have used PNGase F for deglycosylation, as measurements of tryptic peptides deglycosylated by PNGase F failed to robustly differentiate nonglycosylated from deglycosylated versions of the same peptide (Xu et al. 2015). We were able to identify 170 high confidence glycosylation sites corresponding to 103 glycoproteins, of which four were novel glycoproteins (Gpi12o, Chs7p, Heh2p and Osw7p) (Supplementary Table 1). Most of glycoproteins were represented with either one or two glyco-peptides, the exception were glycoproteins like Pdi1p, Ape3p, Fet3p, Plb1p, Ero1p, Plb2p and Rax2p that were represented with four or more glyco-peptides. These results were the basis for a PRM-based approach, where glyco-peptides were monitored together with the peptides without glycosylation sequon belonging to the same glycoprotein.

To test whether we are able to target the peptides identified in the shotgun analysis but omitting the glyco-peptide enrichment step, we mixed yeast wild type cells grown in medium with heavy arginine and lysine isotopes with cells grown in medium with light arginine and lysine isotopes in an equal ratio and performed targeted PRM analysis (Figure 1). Samples enriched for microsomal fractions were digested with LysC and Trypsin proteinases and EndoH was used to generate single GlcNAc glycopeptides. Of 170 glyco-peptides corresponding to 103 glycoproteins measured in the enriched samples we were able to detect 62 belonging to 43 glycoproteins in the unenriched samples from three biological replicates with high confidence (i.e. co-elution of light and heavy peaks, good correlation of relative intensity of specific fragment ions with the reference library, reproducible retention times across different samples) (Table 1).

Figure 1. Schematic representation of SILAC PRM MS assay development.

During discovery phase yeast cells were grown in light medium, microsomal fractions were prepared using previously published method (Mueller et al. 2015) and proteins digested with LysC and trypsin proteinases. Glycan containing peptides were enriched using SPE ZIC-HILIC method (Neue et al. 2011) prior to glycan release with Endo H endoglycosidase. Glyco-peptides containing previously glycosylated asparagine residues tagged with a single GlcNAc residue were identified using shotgun proteomics. Obtained data was used for PRM assay build up where yeast cells were grown in light medium and mixed 1:1 with the cells grown in heavy medium. Membrane derived peptides were prepared as described above, glycans were released with EndoH and targeted PRM analysis was performed.

As it is known that changes in glycosylation can have an impact on glycoprotein steady-state levels, we determined the relative protein abundance as well (Helenius & Aebi 2004; Molinari 2007). In order to quantify protein abundance of each targeted glycoprotein in our analysis, we extended the target list by adding up to two peptides without glycosylation sequon for each glycoprotein analysed. In the final set-up, the full analytical list consisted of 62 glyco-peptides and 74 peptides without glycosylation sequon corresponding to 43 glycoproteins (Appendix Table 1). Furthermore, to account for any variance during mixing of light and heavy cells we also targeted peptides belonging to the ribosomal proteins Rpl5 and Rsp1, respectively. To ensure high-quality quantification of low abundance proteins and proteins containing peptides with poor MS properties, such proteins were analysed using a PRM method with higher resolution (Appendix Table 1). The simultaneous accurate quantification of modified peptides as well as peptides that do not contain a glycosylation sequon enabled us to follow changes in the occupancy of the glycosylation sites analysed as well as relative glycoprotein abundance.

Table 1. List of all glycoproteins and the corresponding glycosylated peptides used in the SILAC PRM-MS analysis of N-linked glycosylation occupancy.

Evaluation of the functional studies of the glycosylation machinery

To validate the newly developed SILAC PRM MS method, we investigated the roles of the Ost3 and Ost6 subunits in OST function *in vivo*. It has been described previously that these subunits with oxidoreductase activity facilitate glycosylation in a site-specific manner (Schulz et al. 2009; Xu et al. 2015; Yeo et al. 2016). As yeast OST contains either Ost3p or Ost6p, we generated strains where either the OST3 or OST6 loci were deleted. Overexpression of plasmid-encoded OST3 or OST6 ensured normal levels of uniform OST (Spirig et al. 2005). This allowed us to compare the phenotype of strains expressing either Ost3p- or Ost6p-containing OST complexes at equal levels. Equal amounts of wild type reference cells grown in heavy medium and of cells with a deletion in one OST subunit grown in light medium were pooled. Cells were lysed, membranes collected, proteins prepared for MS, and light-to-heavy ratios for all peptides measured by PRM. Glyco-peptide abundance relative to wild type was calculated. Values were normalized to the average of two control proteins, Rps1 and Rpl5 and to the average of peptides without glycosylation sequon belonging to the same glycoproteins (Supplementary Table 2).

Figure 2. Glycosylation occupancy analysis at different glycosylation sites of various OST mutant strains and $\Delta alg9$ strain compared to wild type cells.

OST mutant cells, $\Delta ost3$, $\Delta ost3$ complemented with OST6, $\Delta ost6$ and $\Delta ost6$ complemented with OST3, and cells deleted in ALG9 loci were grown in light medium, mixed 1:1 with the wild type reference strain grown in heavy medium and membrane derived peptides were prepared. Peptide abundance was measured by PRM MS. Intensity ratios of glycosylated light to heavy peptides were normalized for expression differences in mutant cells and wild type cells. The resulting ratios represent the site occupancy for the mutant cells relative to the wild type reference strain presented in a heatmap. Data is the mean \pm SE of biological triplicates. Colour is mapped from black (0%) to red (100%), grey is for data not being obtained. Data from Supplementary Table 2.

SILAC PRM MS analysis revealed that 84% of the glycosylation sites were hypoglycosylated (where the glycosylation occupancy ratio compared to wild type reference strain was lower than 0.75) in the strain

lacking Ost3 protein, whereas less severe hypoglycosylation was observed in the strain with OST6 being overexpressed with 39% of the glycosylation sites being hypoglycosylated (Figure 2). Severe hypoglycosylation in $\Delta ost3$ strain was therefore a combination of a reduced level of fully assembled OST and the lack of OST3 function. These results highlight the importance of using yeast strains expressing normal amounts of fully assembled OST, but lacking either Ost3p or Ost6p for the functional analysis of these subunits. The extent of hypoglycosylation is only mild in strains lacking Ost6p, where only 2% of the glycosylation sites were hypoglycosylated in combination with overexpressed OST3. These results indicated that Ost3p-containing complex has a broader substrate specificity as compared to Ost6p-containing complex (Figure 2). The data are in agreement with previously published work demonstrating that Ost3p has a more evident role in N-linked glycosylation compared to Ost6p (Schulz & Aebi 2009; Schulz et al. 2009; Jamaluddin et al. 2014; Yeo et al. 2016). Ost3p affects polypeptide substrate specificity, as in a strain with Ost6p-containing OST only a hypoglycosylation on a subset of glycosylation sites (24 out of 62 sites analysed, corresponding to 21 out of 43 glycoproteins) was observed (Supplementary Table 2). We detected 17 novel Ost3p substrates (Supplementary Table 2, in bold italic), where the glycosylation of these protein substrates was dependent on the presence of the Ost3 subunit. Interestingly, when we examined Ost3p substrates with available structure or structural model, the majority of these proteins required oxidative folding (disulfide bond formation) (data not shown). These results are in accordance with previously proposed function of Ost3 protein to transiently form mixed disulfide bonds with OST polypeptide substrates (Schulz et al. 2009; Mohd Yusuf et al. 2013).

An alternative way to affect OST activity *in vivo* is to prevent complete synthesis of the lipid-linked oligosaccharide substrate (Burda & Aebi 1999). Yeast Alg9p has a dual role in LLO biosynthesis. It is responsible for the addition of two α -1,2-linked Man residues, whereby the assembly of b-branch is a requirement for the assembly of c-branch (Frank & Aebi 2005). We generated a strain where ALG9 loci was deleted, resulting in the accumulation of Man₆GlcNAc₂ LLO and determined site-specific glycosylation efficiencies. As expected, in the *alg* mutant strain many sequons were not efficiently glycosylated and the level of hypoglycosylation was increased as compared to the strain lacking Ost3p complemented with OST6 (Figure 2). Absence of Alg9p resulted in hypoglycosylation (glycosylation lower than 0.75) of 64% of the sites analysed, whereas the lack of Ost3p complemented with OST6 resulted in hypoglycosylation of 39% of the sites analysed (Supplementary Table 2). Although more severe as compared to the loss of Ost3p complemented with OST6, the effect of suboptimal glycan donor appears to have a site specific effect on the OST activity as more than one third of the sites in our analysis were not affected when the ALG9 loci was deleted.

Figure 3. N-glycosylation efficiency is influenced by the primary protein sequence surrounding the glycosylation site.

Two sample logo analysis (Vacic et al. 2006) was used to calculate and visualize residues surrounding glycosylation sites that are significantly enriched in either efficiently or poorly glycosylated sites in *Δost3* complemented with OST6 (A) and *Δalg9* (B) strains. Sequence size analysed contained ten amino acids upstream and downstream from the glycosylation site. Efficiently glycosylated sites are considered where glycosylation occupancy ratio compared to wild type is more than 0.75 and poorly glycosylated sites are considered where glycosylation occupancy ratio compared to wild type is less than 0.25.

In order to examine if the presence of specific amino acids in the local environment of the glycosylation sites influenced N-glycosylation efficiency, sequence analysis was performed on glycosylation sequons plus ten residues upstream and downstream from the glycosylation sites. Two sample logo analysis (Vacic et al. 2006) was used to visualize differences between efficiently and poorly glycosylated sequences surrounding the glycosylation sites. Glycosylation efficiency of Ost6-containing OST (in *Δost3* strain complemented with OST6) was not dependent on the presence of specific amino acids in the local surrounding of the glycosylation site (Figure 3A). In contrast, poorly glycosylated sites in *Δalg9* strain were enriched in N-X-S sequons, as compared to the more efficiently modified N-X-T sequons (Figure 3B). Sequons that contain glutamic acid at +1 position are also less likely to be efficiently glycosylated. Furthermore, sites that are surrounded by basic arginine and lysine residues and polar amino acids appear to be disfavoured when OST is presented with a suboptimal glycan donor. When

we examined the localization of efficiently glycosylated sites in respect to their structural environment, for the substrates with available structure or structural model, we discovered that the glycosylation efficiency was not dependent on the type of secondary structures glycosylation sites were placed on in $\Delta ost3$ strains nor $\Delta alg9$ strain (data not shown).

Based on our results, we concluded that the SILAC PRM MS method was a reproducible, sensitive and useful approach for determining the efficiency of the N-linked glycosylation machinery in yeast.

Protein structural domains influence protein specific glycosylation efficiency

Our novel analytical approach allowed us to analyse the N-glycosylation process of defined proteins in more detail. In particular, we followed the modifications of the ER resident protein disulfide isomerase, Pdi1p that carries five N-linked glycans. Pdi1p is composed of four thioredoxin folds termed a, b, b' and a' that can fold independently (Tian et al. 2006). The a and a' domains contain two and one disulfide bonds, respectively, one per domain is directly involved in the catalytic activity of the isomerase. The five glycosylation sites are located in domain a (2 sites), b (2 sites) and a' (1 site), all of them in structured area of the protein: site 1 (N82, domain a) and site 2 (N117, domain a) are placed in structured loops, site 3 (N155, domain b), site 4 (N174, domain b) and site 5 (N425, domain a') are in α -helices (Tian et al. 2006) (Figure 4).

Glycosylation occupancy of any of the five sites was not severely affected in strains lacking Ost6p, except for site one (N82) being hypoglycosylated in $\Delta ost6$ strain. This hypoglycosylation was rescued by overexpression of OST3. However, absence of the OST3 component had strong, but site-specific effects on Pdi1p glycosylation. In the $\Delta ost3+pOST6$ strain, sites one (N82), two (N117) and five (N425) were hypoglycosylated in the absence of Ost3p (with 0.70, 0.20 and 0.47 glycosylation occupancy, respectively). We noted that these three sites are located in the a and a' domains of the protein that contain disulfide bonds (Tian et al. 2006). Sites three (N155) and four (N174), located in the b domain, were not hypoglycosylated (Figure 4). Pdi1p glycosylation occupancy analysis in $\Delta alg9$ strain revealed similar results as in $\Delta ost3+pOST6$ strain, where the glycosylation of sites one (N82), two (N117) and five (N425) was more severely affected as compared to sites three (N155) and four (N174) (Figure 4).

Figure 4. Site-specific glycosylation occupancy of Pdi1p is influenced by the localization of glycosylation sites in respect of distinct protein domains.

Glycosylation occupancy ratio compared to wild type at five N-linked glycosylation sites (N82, N117, N155, N174 and N425) of Pdi1p in $\Delta ost3$, $\Delta ost3$ complemented with OST6, $\Delta ost6$, $\Delta ost6$ complemented with OST3 and $\Delta alg9$ cells. Values are a mean of biological triplicates. Error bars show SEM. * $p < 0.05$. Pdi1p protein structure is modified from Tian et al. 2001 Cell. Data from Supplementary Table 3.

Defects in LLO biosynthesis lead to changes in ergosterol pathway

We determined the relative protein abundance of glycoproteins across different strains and measured by PRM MS peptides without glycosylation sequon belonging to 62 glycoproteins (Supplementary Table 3). We noted a correlation between hypoglycosylation and unfolded protein response: $\Delta ost3$ strains and $\Delta alg9$ strain displayed the most significant increase of six proteins known to be controlled by this regulatory network (Ero1p, Rot1p, Lhs1p, Pdi1p, Mcd4p and Eps1p). The majority of these proteins act as molecular chaperons and are involved in either ERAD or UPR (Travers et al. 2000; Masato et al. 2008). However, one particular protein, ERG3 C-5 sterol desaturase, involved in ergosterol biosynthesis, showed a 4-fold increase in abundance in $\Delta alg9$ strain only and not in strains with mutations affecting OST components (Figure 5A and 5B; Supplementary Table 3).

Because the initial steps in dolichol (the lipid involved in LLO biosynthesis) and ergosterol biosynthesis are connected, we investigated whether defects in LLO assembly affect other proteins involved in sterol biosynthesis (Chojnacki & Dallner 1988). PRM assays were developed to analyse the abundance of enzymes required in the mevalonate, ergosterol or dolichol pathways (Appendix Table 2). Peptides belonging to 20 out of the 26 proteins were identified and quantified (Figure 5A, black). We also included an *alg3* mutant strain in the analysis. Yeast Alg3p is a α -1,3 mannosyltransferase responsible for the initiation of glycosylation on the LLO b-branch at the ER luminal side, which is then subsequently elongated by Alg9p (Burda & Aebi 1999). Protein abundance of Erg3p protein showed a 3 to 3.5-fold increase in both $\Delta alg3$ and $\Delta alg9$ strains, suggesting that the changes in protein levels of this protein are a result of general defects in LLO assembly (Figure 5C). Moreover, the abundance of three other proteins (Erg11, Erg25 and Erg5, respectively), all acting in ergosterol biosynthetic pathway, showed an increased protein level ratio compared to wild type cells in both $\Delta alg3$ and $\Delta alg9$ strains. Additionally, Erg1p was significantly increased in $\Delta alg3$ strain (Figure 5C). Both defects in LLO assembly resulted in a 3- to 4-fold increase in protein amounts of Erg11p, Erg25p and Erg3p and 1-to 2-fold increase of Erg5p. Earlier measurements using promoter fusions and mutations that alter sterol biosynthesis found upregulation of genes encoding for the same proteins in various genetic backgrounds (Smith et al. 1996; Kennedy et al. 1999; Henry et al. 2002). Furthermore, exposure of yeast cells to sterol inhibitors upregulated the expression of the same genes as well (Bammert & Fostel 2000). To examine if the same phenotype was observed using our proteomic setup, we treated wild type yeast cells with miconazole, an inhibitor of lanosterol 14- α -demethylase Erg11p (Figure 5A) (Joseph-Horne & Hollomon 2006). Equal amounts of wild type cells grown in heavy medium and of cells treated with miconazole or DMSO were pooled and processed as described above. The protein levels were normalized to the ones of the control cells treated with DMSO (Supplementary Table 4).

Similar to strains defective in LLO assembly, the same proteins displayed a significant increase in protein level ratio compared to cells, including proteins Erg11, Erg25, Erg3 and Erg5 (Figure 5C).

Figure 5. Protein abundance of several ergosterol pathway proteins is influenced by defects in dolichol pathway.

(A.) Schematic representation of mevalonate, ergosterol and dolichol pathway (adapted from Grabińska & Palamarczyk 2002; Liang et al. 2009). (B.) Deletion of *ALG9* loci results in increased abundance of several proteins involved in UPR as well as Erg3p. $\Delta alg9$ cells were grown in light medium, mixed 1:1 with the wild type reference strain grown in heavy medium and membrane derived peptides were prepared. Peptide abundance was

measured by SILAC PRM. Intensity ratios of light to heavy peptides were normalized for expression differences in mutant cells and wild type cells. The resulting ratios represent the protein abundance for the mutant cells relative to the wild type reference strain. Data is the mean \pm SE of biological triplicates. Data from Supplementary Table 3. (C.) Deletion of *ALG9* and *ALG3* loci, as well as treatment of cells with sterol inhibitor miconazole results in increased protein abundance of multiple ERG proteins. $\Delta alg9$, $\Delta alg3$, cells treated with miconazole or DMSO were grown in light medium, mixed 1:1 with the wild type reference strain grown in heavy medium and membrane derived peptides were prepared. Peptide abundance was measured by PRM MS with an inclusion list containing peptides belonging to mevalonate, ergosterol and dolichol pathway proteins. Data was normalized to the data obtained for control cells treated with DMSO. Data is the mean \pm SE of three biological triplicates. Data from Supplementary Table 4.

Discussion

N-linked glycosylation machinery, with OST as the central enzyme, modifies many proteins with glycans that can be fundamental in many different ways for cell viability, yet the crucial mechanisms responsible for the regulation of N-linked glycosylation are not well understood. To increase the resolution of measurement of OST function *in vivo*, we developed a novel analytical tool to quantify relative N-glycosylation occupancy at many glycosylation sites in different membrane and luminal proteins. We have shown that its sensitivity and consistency make PRM MS especially suitable for the analysis of N-linked glycoproteins, sometimes present in medium to low amounts in the cell. Coupled with SILAC our approach offers a powerful analytical tool to study the efficiency of N-linked glycosylation machinery in a sensitive, effective and reproducible way providing results that were in agreement with previously published data. Our method is a complementary analytical approach to the recently reported methods where SWATH and SWAT MS were used to quantify relative glycosylation occupancy of a lower number of predefined glycosylation sites in glycoproteins extracted from yeast cell wall (Xu et al. 2015; Yeo et al. 2016; Zacchi & BL Schulz 2016). Compared to other approaches, the analysis of yeast membrane and luminal glycoproteins eliminates the analytical bias present in the complementary approaches where only mature, successfully secreted proteins from yeast cell wall extracts are analysed (Schulz & Aebi 2009). We are now able to investigate the glycosylation extent of glycoproteins involved in N-linked glycosylation, ERQC and UPR, in a resolved, quantifiable and reproducible way. Simultaneous analysis of protein abundance allows us to examine distinct influence of glycosylation on steady-state levels of individual substrate proteins or a global influence evident in ERQC and UPR activation.

We have used this approach to investigate protein substrate specificities of OST isoforms containing either Ost3p or Ost6p. In agreement with other reports, both isoforms affected OST substrates specifically and displayed site-specific preferences for a subset of glycosylation sites. This effect was not caused by a general reduction in OST activity as distinct sites were affected in the absence of Ost3p or Ost6p (Schwarz et al. 2005; Schulz et al. 2009). Furthermore, Ost3p was required for efficient glycosylation of more than a third of glycosylation sites analysed here, compatible with a broader substrate array as compared to Ost6p isoform (Schulz & Aebi 2009; Xu et al. 2015; Yeo et al. 2016; Zacchi & BL Schulz 2016). We were able to detect novel Ost3p substrates and a majority of these protein substrates required oxidative folding. It has been demonstrated that both Ost3 and Ost6 subunits have thioredoxin-like domains that transiently interact with their protein substrates through mixed disulfide bonds (Mohorko et al. 2014). However, the importance of noncovalent interactions has been demonstrated as well, explaining why Ost3p influenced glycosylation at asparagines in

substrate proteins that do not contain disulfide bonds (Fetrow et al. 2001; Schwarz et al. 2005; Schulz et al. 2009; Jamaluddin et al. 2011; Mohd Yusuf et al. 2013; Jamaluddin et al. 2014).

In the process of N-linked glycosylation the OST enzyme displays a preference for both the polypeptide substrate and LLO donor, where suboptimal LLO structures are utilized, although will lower efficiency (Burda & Aebi 1999). We have examined the effect of the Man₆GlcNAc₂ suboptimal glycan donor generated in *Δalg9* strain on the glycosylation efficiency of OST *in vivo*. Absence of Alg9p resulted in a more severe hypoglycosylation phenotype as compared to the loss of Ost3p complemented with OST6. Furthermore, the presence of a suboptimal glycan donor had a site-specific effect on the OST activity. This effect was not dependent on the protein secondary structure, e.g. the folding of the acceptor protein. However, glycosylation efficiency was sensitive to the primary sequence of the OST substrate: in *Δalg9* strain, poorly glycosylated sites were enriched in N-X-S sequons as compared to the more efficiently modified N-X-T sequons. Crystal structure of PglB, a single subunit OST from *Campylobacter jejuni*, a homolog of the STT3 subunit of multi-subunit OSTs revealed that the WWD domain, not directly involved in the catalysis, bound the N-X-T sequon more efficiently (Lizak et al. 2011). We propose that the combination of a suboptimal LLO substrate and the low affinity sequon N-X-S is the cause for the reduced glycosylation of these sites. Similarly, our analysis revealed that sites that have a negative charge at X position and sites that are adjacent to basic and polar amino acids were disfavoured when OST was presented with a suboptimal glycan donor. Therefore, the analysis of site-specific N-glycosylation in *alg* mutant strains revealed a peptide substrate preference of the OST. Importantly, this preference was not observed in *ost3* or *ost6* mutant strains. Glycosylation efficiency of Ost3/Ost6p-containing OSTs did not reveal a site specificity indicating that Ost3 and Ost6 subunits are not involved in defining the general polypeptide binding affinity of OST. Kinetic experiments with yeast OST have revealed that there is a single binding site for the polypeptide substrate while the LLO substrate is bound in a cooperative manner (Karaoglu et al. 2001; Daniel J Kelleher et al. 2003; Kelleher et al. 2007). A substrate activation model suggests that the binding of the LLO donor substrate to the regulatory LLO binding site is a prerequisite for the binding of both the polypeptide substrate and second LLO donor substrate to the catalytic site (Karaoglu et al. 2001). We have shown that the accumulation of suboptimal LLO donor substrate in *Δalg9* strain influenced the polypeptide preference of OST, which is in agreement with this model.

The possibility to investigate the status of all glycosylation sites of Pdi1p, an ER-resident protein whose protein structure is known, allowed us to analyse the N-glycosylation process in more detail. N-linked glycosylation of sites located in two domains of Pdi1p that also contain disulfide bonds (a and a' respectively) were Ost3p dependent, where the site closest to the non-active disulfide bond (site two, N117) was the one most affected in the cells lacking Ost3p. We conclude that the formation of a mixed

disulfide between Ost3p and Pdi1p slows down the folding and increases the glycosylation efficiency of this sequon. Protein folding is a critical competitor of N-linked glycosylation and indeed, the N117 site of Pdi1p is located in a protein sequence with secondary structure not competitive with N-glycosylation. The same site of Pdi1p is also hypoglycosylated in $\Delta alg9$ strain, supporting our hypothesis that reducing OST activity affects sites where folding is in competition with glycosylation. On the other hand, glycosylation of sites three (N155) and four (N174) was not affected as compared to other sites in *ost3/6* or *alg9* cells even though sites three and four are located in α -helices. Folding of the b domain might be slower than the folding of the a and a' domains, leaving an OST with enough time to efficiently glycosylate sequons present in this regions. Alternatively, additional OST components might prevent rapid folding of this domain.

Glycosylation and folding of proteins in the ER co-evolved and suboptimal glycosylation can affect the folding of specific proteins. In a system where not properly folded proteins are degraded this leads to an altered steady-state level of glycoproteins (Varki 1993; Larkin & Imperiali 2011; Zattas & Hochstrasser 2015). In addition, the unfolded protein response (UPR) can be activated (Chapman et al. 1998; Travers et al. 2000). We observed reduced steady-state level upon reduced glycosylation ($\Delta alg9$) for only a few glycoproteins tested (Yjr1p, Yl413p, Ape3p, Pdr5p) but we detected an upregulation of the know UPR proteins such as Rot1p, Ero1p, Pdi1p (Figure 5). The largest increase in abundance was observed for Erg3p in the $\Delta alg9$ strain, which was not a result of UPR activation nor hypoglycosylation as the level of this protein was not altered in any other mutant strain, such as $\Delta ost3$ or $\Delta ost6$, tested. We showed that the deficiency in LLO assembly affected several other enzymes involved in the ergosterol but not mevalonate pathway. Genes encoding for the upregulated proteins were found previously to be upregulated upon mutations that altered sterol biosynthesis or upon exposure to sterol inhibitors and we were able to increase the steady-state levels when cells were treated with the sterol biosynthesis inhibitor miconazole. We postulate a regulatory mechanism that links the LLO biosynthetic pathway with ergosterol biosynthesis. In view of the topology of the different pathways involved, we postulate that dolichyl pyrophosphate might act as a mediator in this regulation process. However, more experiments have to be performed to confirm this hypothesis.

In summary, the SILAC PRM MS method provided adequate selectivity and sensitivity for the quantitative analysis of a large number of glycosylation sites on yeast N-glycoproteins. Compared to other analytical methods, our assay allowed detection of novel Ost3p and Ost6p glycoprotein substrates and made it possible to target specific substrates such as Pdi1p for a more detailed analysis. The targeted analytical approach, in combination with a time resolved SILAC approach, will be instrumental for a detailed description of the role of N-glycosylation in the *in vivo* protein maturation at a molecular level.

Materials and Methods

Yeast strains and growth conditions

All yeast strains and plasmids used in this study are listed in Supplementary Table 5 and 6. Standard yeast genetic techniques were used (Güldener et al. 1996; Knop et al. 1999). All yeast strains were grown in an orbital shaker at 30°C and 180rpm to exponential phase (OD_{600nm} 1.0).

For MS assay, cells were grown in appropriate synthetic drop-out (SD) medium (0.67% (w/v) yeast nitrogen base, 2% (w/v) glucose with appropriate amino acid supplements) containing either 20 mg/L of light or heavy isotopes of arginine (13C6) and lysine (13C6-15N2) (Cambridge Isotope Laboratories). Cells were collected, frozen in liquid nitrogen and stored at -80°C.

For sterol inhibition assay, mid-log phase cultures of the wild type yeast cells in light SD medium were exposed to miconazole (0.3 µg/mL, dissolved in DMSO; Janseen Geel) while the controls received an equivalent amount of DMSO. After 2.5 hours, cells were washed once with ice cold 50 mM sodium acetate, 10 mM EDTA buffer (pH 4.5) before they were collected, frozen in liquid nitrogen and stored at -80°C.

Sample preparation for mass spectrometry

Membrane proteins were prepared as described (Mueller et al. 2015). In brief, yeast cells were lysed at 4°C using glass beads, and the microsomal fraction was pelleted by centrifugation (16000 x g; 20 min), resuspended in 0.1 M Na_2CO_3 , 1 mM EDTA, pH 11.3 buffer and pelleted again. Samples were resuspended in SDS buffer (2% SDS (w/v), 50 mM DTT, 0.1 M Tris HCl pH 7.6) and processed using the filter assisted sample preparation protocol (Wiśniewski et al. 2009). Membrane proteins were digested first with endopeptidase LysC (20 µg/ml; Wako Pure Chemical, Richmond, VA) at room temperature for 16 h followed by digestion with trypsin (20 µg/ml; Promega) at 37°C for 4 h. For shotgun experiments in the discovery phase of PRM assay development, sample was enriched for glycopeptides using SPE ZIC-HILIC (SeQuant) column as described before (Neue et al. 2011). For PRM experiments protein digestion was directly followed by digestion of N-glycans with endo-β-N-acetylglucosaminidase H (EndoH; 500 U; New England Biolabs) in sodium citrate buffer (50 mM, pH 5.5) at 37°C with agitation for 40 h. Peptides were desalted using Sep Pak C18 classic (Waters) and dried using speed vacuum. Desalted peptides were resuspended in ACN/H₂O (3:97 (v/v)) with formic acid (FA; 0.1% (v/v)) and analysed by LC-ESI-MS/MS.

Shotgun and targeted proteomics analysis

Mass spectrometric analysis

Samples were subjected to a Q Exactive HF mass spectrometer (Thermo Scientific) coupled to a nano EasyLC 1000 (Thermo Fisher Scientific) system and to an Acquity UPLC M-class System (Waters). Samples were loaded onto a self-made column (75 μm \times 150 mm) packed with reverse-phase C18 material (ReproSil-Pur 120 C18-AQ, 1.9 μm , Dr. Maisch GmbH) when the EasyLC 1000 was coupled. ACQUITY UPLC M-Class column (75 μm \times 150 mm) packed with reverse-phase C18 material (Waters HSS T3 100 C18, 1.8 μm) was used when the Acquity UPLC M-class system was coupled. Peptides were separated at a flow rate of 300 nL/min using a linear gradient of 1% to 35% solvent B (0.1% formic acid in acetonitrile) over 90 min, followed by an increase to 98 % B over 2 min and held at 98 % B for 5 min before returning to initial conditions of 1% B.

In shotgun-MS, the mass spectrometer was set to acquire full-scan MS spectra (300-1700 m/z) at a resolution of 60000 after accumulation to an automated gain control (AGC) target value of $3e^6$ and a maximum injection time of 15 ms. Charge state screening was enabled and unassigned charge states and single charged precursors were excluded. Ions were isolated using a quadrupole mass filter with a 1.2 m/z isolation window. A maximum injection time of 45 ms was set. HCD fragmentation was performed at a normalized collision energy (NCE) of 28 %. Selected ions were dynamically excluded for 20 sec.

For PRM measurements, the Q Exactive HF performed MS₁ scans (400-1200 m/z) followed by 12 MS/MS acquisitions in PRM mode. The full scan event was collected at a resolution of 60 000 (at m/z 400) and a AGC value of $3e^6$ and a maximum injection time of 120 ms. The PRM scan events used an Orbitrap resolution of 30 000 or 60 000, maximum fill time of 55 ms or 110 ms respectively, with an isolation width of 2 m/z and an AGC value of $2e^5$. HCD fragmentation was performed at a normalized collision energy (NCE) of 28 % and MS/MS scans were acquired with a starting mass of m/z 120. Scan windows were set to 10 min for each peptide in the final PRM method to ensure the measurement of 6–10 points per LC peak per transition. All samples were analysed using two PRM methods based on scheduled inclusion lists containing the 175 target precursor ions, including Biognosys iRT standard peptides, at an Orbitrap resolution of 30 000 and two PRM methods based on scheduled inclusion lists containing the 128 target precursor ions, including Biognosys iRT standard peptides, at an Orbitrap resolution of 60 000 (Appendix Table 1).

Protein identification and spectral library building

MS and MS/MS spectra generated from enriched and non-enriched glycopeptides extracts were converted to Mascot generic format (MGF) using Proteome Discoverer, v2.1 (Thermo Fisher Scientific, Bremen, Germany). The MGFs were searched with Mascot Server v.2.4.1 (www.matrixscience.com) using the following parameters: a precursor ion mass tolerance of 15 ppm, product ion mass tolerance of 0.05 Dalton, and as variable modifications methionine oxidation, carbamidomethylation of cysteine and asparagine N-linked HexNAc (CID/HCD) glycosylation for the glyco-enriched samples. Searches were made against the *Saccharomyces cerevisiae* reference proteome database, concatenated to a reversed decoyed FASTA database and 260 common protein contaminants. The Mascot search results (dat. files) were imported into the Skyline software (v2.6.0) (MacLean et al. 2010) and spectral libraries were built using the BiblioSpec algorithm (Frewen & MacCoss 2007). Additionally published spectral libraries (Selevsek et al. 2015) were used to populate the final PRM assays. For glyco-peptides where ion libraries could not be obtained at the time, fragment ions were manually selected based on MS2 spectra obtained directly from the mascot search results.

Data processing and analysis

Skyline software (v2.6.0) with standard settings was used for data processing (MacLean et al. 2010). The abundance of peptides was analysed by summing the integrated areas of at least four fragment ions per peptide. Peptide peaks were analysed manually, and correct identification was assigned on the basis of the following criteria: (i) retention time matching to spectral library within 5% of the gradient length, (ii) co-elution of light and heavy peptides, (iii) dot product between light peptide precursor ion isotope distribution intensities and theoretical, (iv) dot product between library spectrum intensities and light peptides, and (v) matching peak shape for precursor and product ions from light and heavy peptides. The reported light to heavy intensity ratios (L/H) were normalized for proportionate mixing of heavy labelled with light labelled cells, by dividing the L/H intensity ratio of all measured peptides by the median of L/H intensity reported for four peptides belonging to two control proteins, Rps1a and Rpl5. L/H ratio for glyco-peptides modified with HexNAc was used to calculate the relative site occupancy for the given peptide/ glycosylation site compared to the wild type reference strain. The relative site occupancy was normalized for expression differences between heavy labelled wild type reference strain (H) and the mutant light strains (L) by dividing the L/H intensity ratio for the occupied glyco-peptide by the median of L/H intensity ratios reported for all peptides that do not containing a NxT/S sequon from the same protein. Protein level quantification was calculated as the median of L/H intensity ratios reported for all peptides without glycosylation sequon belonging to the

same protein, normalized for proportionate mixing of heavy labelled with light labelled cells as described above.

PRM MS quantification of ergosterol pathway protein abundance

SWATH-MS data published earlier (Selevsek et al. 2015) was used as ion library source to build a PRM assay for targeted analysis of ergosterol pathway proteins. Ion library information for peptides belonging to 20 from 26 proteins known to be involved in mevalonate, ergosterol and dolichol pathway were extracted and targeted PRM analysis was performed on Q Exactive HF mass spectrometer as described before. Scheduled inclusion list contained 100 target precursor ions, including Biognosys iRT standard peptides (Appendix Table 2).

The abundance of peptides was analysed using Skyline software with standard settings, where peptide peaks were analysed manually as described above. The reported L/H intensity ratios were normalized for proportionate mixing of heavy labelled with light labelled cells, by dividing the L/H intensity ratio of all measured peptides by the median of L/H intensity reported for peptides belonging to two control proteins, Rps1a and Rpl5. Protein level quantification was calculated as the median of L/H intensity ratios reported for all peptides belonging to the same protein. In the case of sterol inhibition assay, resulting protein abundance was further normalized to the protein abundance of the control samples treated with DMSO.

Chapter 3

Analysis of Substrate Specificity of *Trypanosoma brucei* OST by Functional Expression in Yeast

Kristina Poljak, Jörg Breitling, Robert Woodward, Amirreza Faridmoayer, Rober Gauss, George Rugarabamu, Mauro Pellanda, and Markus Aebi

Contributions:

Preparation of samples for mass spectrometry.

PRM MS measurements.

Data analysis.

Writing the manuscript.

Note:

The first part of this chapter, regarding LLO specificity of different *Tb*STT3 enzymes, has already been published in the PhD thesis of Jörg Breitling. The manuscript has been further extended by Kristina Poljak.

Summary

N-linked protein glycosylation is an essential and highly conserved post-translational modification in eukaryotes. The transfer of a glycan from a lipid-linked oligosaccharide (LLO) donor to asparagine residues of nascent polypeptide chains is catalysed by the oligosaccharyltransferase (OST) in the lumen of the endoplasmic reticulum. *Trypanosoma brucei* encodes three paralogue single protein OSTs called *TbSTT3A*, *TbSTT3B* and *TbSTT3C* that can functionally complement the *Saccharomyces cerevisiae* OST. We characterised the LLO specificity of all three OST isoforms in the heterologous expression host *S. cerevisiae* and demonstrated that *TbSTT3A* accepted LLO substrates ranging from $\text{Man}_5\text{GlcNAc}_2$ to $\text{Man}_7\text{GlcNAc}_2$. In contrast, *TbSTT3B* required $\text{Man}_6\text{GlcNAc}_2$ to $\text{Glc}_3\text{Man}_9\text{GlcNAc}_2$ structures while *TbSTT3C* did not display any LLO preference. Besides this substrate specificity *in vivo*, we show that all *T. brucei* OST transfer the short substrate GlcNAc_2 with equal affinity. We identified regions within different OST proteins that influence the specificity towards the LLO and polypeptide substrate.

Introduction

Asparagine-linked protein glycosylation (N-glycosylation) is a highly conserved posttranslational modification in eukaryotes. N-glycosylation is an essential process and plays important roles in protein folding quality control, cell-cell interactions and developmental processes (Lowe and Marth 2003; Helenius and Aebi 2004). The glycans transferred to nascent polypeptide chains in the endoplasmic reticulum (ER) are built on the lipid carrier dolichylphosphate (Dol-P) to yield the lipid-linked oligosaccharide (LLO) substrate for OST. The biosynthesis of the LLO is an ordered, stepwise process conducted by the concerted action of specific glycosyltransferases that are encoded by the asparagine-linked glycosylation (*ALG*) genes. LLO biosynthesis is initiated by the addition of N-acetylglucosaminyl-phosphate and N-acetylglucosamine (GlcNAc) to the lipid carrier on the cytosolic face of the ER membrane using nucleotide activated UDP-GlcNAc as donor to form Dol-PP-GlcNAc₂. Subsequently the LLO is elongated by five mannose (Man) residues. The Man₅GlcNAc₂ LLO is then translocated into the ER lumen. There, Dol-P bound Man serves as donor for the further elongation of the LLO with Man until a Man₉GlcNAc₂ structure is built up. In most of the fungi and animal species the addition of three glucose (Glc) residues on the α -branch from Dol-P-Glc terminates LLO biosynthesis (Burda and Aebi 1999).

The mature Glc₃Man₉GlcNAc₂ LLO is used as donor substrate by the oligosaccharyltransferase (OST) that transfers the oligosaccharide from the lipid carrier *en bloc* to an asparagine residue of a nascent polypeptide chain. In eukaryotes, the acceptor asparagine residue is located within a conserved sequon consisting of three amino acids: asparagine, a second amino acid (any, but proline) and threonine or serine (NxT/S) (Gavel and von Heijne 1990). In multicellular eukaryotes the OST is a complex assembled from eight different proteins with *STT3* encoding the catalytic subunit (Yan and Lennarz 2002; Kelleher et al. 2003; Nilsson et al. 2003). Other subunits of the heterooligomeric complex were suggested to influence OST substrate interactions and complex assembly (Pathak et al. 1995; Spirig et al. 2005; Wilson et al. 2008; Schulz et al. 2009; Roboti and High 2012).

The genomes of the kinetoplastids *Trypanosoma* and *Leishmania* only encode homologues of the yeast *STT3* gene (Kelleher and Gilmore 2006). All other subunits found in heterooligomeric OST complexes of *S. cerevisiae* or mammals are missing in *T. brucei*, *T. cruzi* and *L. major*, suggesting that these proteins function as single subunit OSTs similar to enzymes known from bacterial and archaeal N-glycosylation systems (Wacker et al. 2002; Calo et al. 2010). *S. cerevisiae* has proven to be a suitable heterologous *in vivo* system to functionally express and characterize kinetoplastid OSTs. The yeast cells used in these studies lacked the essential yeast *STT3* subunit or other essential OST subunits. This deleterious loss of a functional yeast OST is complemented by expression of different *STT3* proteins

from *Trypanosoma cruzi*, *Trypanosoma brucei* and *Leishmania major*, demonstrating that these STT3s function as single protein OSTs (Castro et al. 2006; Parsaie Nasab et al. 2008; Hese et al. 2009; Izquierdo et al. 2009).

Trypanosoma brucei is a protozoan parasite causing African sleeping sickness in humans and nagana in cattle. *T. brucei* cells encounter two hosts during their life cycle. The parasite exists as the procyclic form in an insect vector (the tsetse fly) whereas it is referred to as bloodstream form when afflicting the mammalian host. The surface of *T. brucei* cells is covered by glycoproteins termed variant surface glycoprotein (VSG) in the bloodstream form and procyclins in its procyclic life stage. N-linked glycosylation epitopes on VSG play an important role in *T. brucei* virulence (Castillo-Acosta et al. 2016). Furthermore, a possible immune evasion strategy has been proposed where *T. brucei* genetically recombined its N-linked glycosylation machinery, resulting in the change of the glycosylation status of VSG (Castillo-Acosta et al. 2013). The *T. brucei* genome encodes three paralogues of *STT3* termed *TbSTT3A*, *TbSTT3B* and *TbSTT3C* (Samuelson et al. 2005; Izquierdo et al. 2009). In contrast to multicellular eukaryotes, trypanosomatids are incapable of synthesising Dol-P-Glc and therefore lack the three capping Glc residues found in yeast and higher eukaryotes (Parodi et al. 1981; de la Canal and Parodi 1987; Samuelson et al. 2005).

The three paralogue STT3s encoded by the *T. brucei* genome display distinct preferences for the LLO donor as well as for the acceptor polypeptide substrate. While *TbSTT3A* was shown to preferentially transfer $\text{Man}_5\text{GlcNAc}_2$ glycans to acceptor polypeptide chains, both *TbSTT3B* and *TbSTT3C* glycosylated acceptor sites with $\text{Man}_9\text{GlcNAc}_2$ glycans (Izquierdo et al. 2009). A recent study performed in *T. brucei* cells extended these findings, reporting that both *TbSTT3A* and *TbSTT3B* transfer $\text{Man}_7\text{GlcNAc}_2$ and $\text{Man}_5\text{GlcNAc}_2$ glycans to a VSG protein (Izquierdo et al. 2012). The authors suggest that the substrate specificity of *TbSTT3A* and *TbSTT3B* is promoted by the presence or absence of the LLO substrate c-branch. The LLO specificity of *TbSTT3C* was not addressed because this paralogue is not expressed in *T. brucei* cells used for the experiments (Izquierdo et al. 2009). Analysis of the OST protein products revealed that *TbSTT3A* and *TbSTT3C* preferentially glycosylate sequons with acidic amino acids in the sequon's vicinity. By contrast *TbSTT3B* did not display a particular preference for glycosylation sequons and the amino acids surrounding them (Izquierdo et al. 2009).

In this study, we used the functional expression of *T. brucei* STT3 proteins in yeast to analyse their function in detail. We took advantage of the "genetic tailoring" (Jakob et al. 1998) of the OST substrate and the quantitative analysis of glycosylation site occupancy (Poljak et al.; in preparation) to characterise *T. brucei* OST function. Domain-swap experiments made it possible to assign functional properties to specific regions of the STT3 proteins.

Results

***TbSTT3A*, *TbSTT3B* and *TbSTT3C* display differential preferences for LLO substrates from $\text{Man}_5\text{GlcNAc}_2$ to $\text{Glc}_3\text{Man}_9\text{GlcNAc}_2$**

In vivo analysis of the *TbSTT3* LLO specificity revealed that *TbSTT3B* transfers primarily $\text{Man}_9\text{GlcNAc}_2$ oligosaccharides, while *TbSTT3A* transfers $\text{Man}_5\text{GlcNAc}_2$ glycans to its preferred glycosylation site of VSG221. Data acquired in the Δstt3 *S. cerevisiae* strain suggested that *TbSTT3B* and *TbSTT3C* both accept $\text{Glc}_3\text{Man}_9\text{GlcNAc}_2$ as LLO substrate, while *TbSTT3A* cannot utilise the $\text{Glc}_3\text{Man}_9\text{GlcNAc}_2$ LLO substrate (Izquierdo et al. 2009). We therefore further investigated the LLO specificity of all three *TbSTT3* paralogues using the heterologous yeast expression system. We combined the *STT3* deletion with different deletions in the LLO biosynthesis pathway (*ALG* genes) in yeast. The $\Delta\text{stt3}\Delta\text{alg}$ strains harbouring the yeast *STT3* (*ScSTT3*) *URA3*-plasmid and a second, *LEU2*-marked plasmid, encoding either *ScSTT3* or the different *TbSTT3* paralogues, were subjected to plasmid shuffling using 5-FOA. In this approach survival of the cells on 5-FOA depended on the ability of the different *TbSTT3* genes, encoded on the *LEU2* plasmids, to complement the yeast *STT3* deletion.

In the $\Delta\text{stt3}\Delta\text{alg3}$ double mutant strain (accumulation of the $\text{Man}_5\text{GlcNAc}_2$ oligosaccharide), only *TbSTT3A* and *TbSTT3C* complemented the *STT3* deletion (Figure 1A). This result is in accordance with the finding that *TbSTT3A* can utilise the $\text{Man}_5\text{GlcNAc}_2$ LLO substrates in *T. brucei* (Izquierdo et al. 2009). Interestingly in both the $\Delta\text{stt3}\Delta\text{alg9}$ and the $\Delta\text{stt3}\Delta\text{alg12}$ strains, all three *TbSTT3* paralogues complemented the deletion of endogenous OST activity (Figure 1B and 1C). In the Δstt3 strain only *TbSTT3B* and *TbSTT3C* complement the *STT3* deletion, while *TbSTT3A* expressing cells did not survive plasmid shuffling (Figure 1E) (Izquierdo et al. 2009). The inability of *TbSTT3A* to complement Δstt3 in the presence of $\text{Glc}_3\text{Man}_9\text{GlcNAc}_2$ LLOs was independent of the three terminal glucose residues on the LLO substrate since growth of $\Delta\text{stt3}\Delta\text{alg6}$ cells expressing *TbSTT3A* was also not rescued (Figure 1D).

Figure 1. LLO specificity of *TbSTT3* paralogues.

Strains deleted for genomic *STT3* ($\Delta stt3$) were complemented by a *URA3*-plasmid encoding yeast *STT3* (ScSTT3). The strains harboured a second, *LEU2*-marked plasmid encoding *TbSTT3A*, *TbSTT3B*, *TbSTT3C*, ScSTT3 or no *STT3* gene (e.v.). Serial dilutions of (A) $\Delta stt3\Delta alg3$, (B) $\Delta stt3\Delta alg9$, (C) $\Delta stt3\Delta alg12$, (D) $\Delta stt3\Delta alg6$ and (E) $\Delta stt3$ were spotted on 5-FOA containing medium and incubated at 23°C for different times to select for *ura*⁻ cells. STT3s encoded on the *LEU2*-plasmid complementing the genomic $\Delta stt3$ deletion support growth on 5-FOA containing medium. LLO structures of the respective strains were depicted schematically. (F) The yeast LLO structure is represented by two GlcNAc (black squares), nine Man (grey circles) and three Glc (black circles) residues with the respective linkages indicated and LLO branches are labelled by a, b and c.

Our data confirm that the complementary activity of the different *T. brucei* STT3 proteins depended on the oligosaccharide structures of the substrate LLO. In particular, the observation that *TbSTT3A* was able to utilise LLO substrates from Man₅GlcNAc₂ up to Man₇GlcNAc₂ but did not accept LLOs with nine Man residues (i.e. in $\Delta stt3\Delta alg6$ and $\Delta stt3$) suggested that c-branch Man residues reduced the use by *TbSTT3A*.

We tested this hypothesis by using $\Delta stt3\Delta alg9$ cells complemented with *TbSTT3* paralogues and overexpressing the yeast *ALG12* gene (p*ALG12*). Overexpression of *ALG12* in $\Delta alg9$ cells resulted in a mixed LLO population consisting of Man₆GlcNAc₂ and Man₇GlcNAc₂ which contains the first c-branch α -1,6 Man residue added by *ALG12* (Figure 1F) (Burda et al. 1999). Protein-linked oligosaccharides (NLOs) were isolated to test whether the *ALG12*-generated triantennary Man₇GlcNAc₂ (Man₇-ALG)

LLO can serve as a substrate for the three *TbSTT3* paralogues to glycosylate substrate proteins. NLOs were enzymatically released from proteins, labelled with 2-AB and analysed by HPLC (Figure 2A to 2D).

The first peak in the HPLC profile of NLOs obtained from the vector control strains corresponded to a $\text{Man}_6\text{GlcNAc}_2$ glycan (Figure 2A to 2D, e.v.). This oligosaccharide represented the $\text{Man}_6\text{GlcNAc}_2$ produced in Δalg9 cells and transferred to proteins by OST. Higher mannose structures resolved in the chromatogram profile ($\text{Man}_7\text{GlcNAc}_2$ up to $\text{Man}_{11}\text{GlcNAc}_2$) reflected the subsequent addition of Man residues to the protein linked $\text{Man}_6\text{GlcNAc}_2$ by Golgi-resident mannosyltransferases (Munro 2001). Overexpression of *ALG12* in an Δalg9 cell altered the LLO composition (Burda et al. 1999) and this was reflected by the altered NLO composition on N-glycoproteins. In all Δalg9 control cells, small amounts of N-glycans larger than $\text{Man}_6\text{GlcNAc}_2$ were detected; they represent $\text{Man}_6\text{GlcNAc}_2$ structures modified in the Golgi (Munro 2001). Overexpression of the *ALG12* mannosyltransferase results in the generation of the triantennary $\text{Man}_7\text{GlcNAc}_2$ LLO substrate (Burda et al. 1999) and in an subsequent increase of the N-linked $\text{Man}_7\text{GlcNAc}_2$ glycans. However, this increase was dependent on the OST present: the endogenous OST (Figure 2A), *TbSTT3B* (Figure 2C) and *TbSTT3C* (Figure 2D) supported this transfer of $\text{Man}_7\text{GlcNAc}_2$ to protein, whereas expression of *TbSTT3A* led to minor alterations of N-glycan composition upon *Alg12p* overexpression (Figure 2B and 2E). We concluded that the α -1,3 Man added by *ALG12* mannosyltransferase reduced the affinity of *TbSTT3A* towards the lipid-linked oligosaccharide.

Figure 2. Analysis of NLOs isolated from $\Delta stt3\Delta alg9$ cells complemented by *TbSTT3* paralogues with or without overexpression of *ALG12*.

2-AB labelled NLOs were isolated from $\Delta stt3\Delta alg9$ cells complemented by (A) *ScSTT3*, (B) *TbSTT3A*, (C) *TbSTT3B* or (D) *TbSTT3C* with (+ *pALG12*) or without overexpression of *ALG12*. Labelled NLOs were separated by HPLC and fluorescence of the 2-AB label was detected (displayed as arbitrary units [AU]). In the resulting NLO profiles $Man_6GlcNAc_2$ (M6) up to $Man_{11}GlcNAc_2$ (M11) glycans were observed using NLOs from RNaseB to assign peak identities. (E) The $Man_7GlcNAc_2$ (Man7) NLO fraction in cells with (+) or without (-) *ALG12* overexpression were calculated and expressed as % of the total peak area of all NLO peaks (M6 to M11) of the individual strains (A-D) \pm standard deviation from three independent experiments (error bars). Values of all peak areas can be found in Supplementary Table 1.

All *TbSTT3* paralogues transfer GlcNAc₂ LLOs to a peptide in vitro

Based on the experiments described above, we concluded that mannosyl residues present on the LLO substrate can alter the substrate specificity of the *T. brucei* OST. We therefore tested the activity of these enzymes towards the minimal GlcNAc₂ (chitobiose) substrate. Due to the lethal phenotype of *Δalg1* mutant strains (Albright and Robbins 1990), we turned to an in vitro assay and used tamra-labelled DANYTK peptide and microsomes from yeast cells deleted for endogenous *STT3* and expressing *TbSTT3A*, *TbSTT3B* or *TbSTT3C*. As LLO substrate we used a chemically synthesized GlcNAc₂ LLO whose lipid component is truncated compared to dolichol of yeast (Supplementary Figure 1A). Activity of the different enzymes was monitored by a shift in peptide mobility upon SDS-PAGE (Figure 3). We demonstrated *in vitro* activity in all cell extracts. For all three *TbSTT3*s activity was dependent on the presence of LLO and microsomes and the reaction was inhibited by EDTA, indicating cation dependence (Supplementary Figure 1B). We used the conversion of the peptide substrate at different LLO concentrations to roughly approximate the apparent k_m values for the LLO substrate and found them to be at the same order of magnitude for all OSTs (approximately 2.5-10 μ M). Interestingly microsomes prepared from yeast wild type cells did not show any activity with the GlcNAc₂ LLO substrate under the conditions used (Supplementary Figure 1C).

Figure 3. *In vitro* glycosylation assay with *TbSTT3A*, *TbSTT3B* and *TbSTT3C* using GlcNAc₂ LLO donor substrate.

TbSTT3A, *TbSTT3B* and *TbSTT3C* were expressed in yeast cells with *ScSTT3* deletion and microsomes were prepared from these cells. Microsomes were incubated with tamra-labelled peptide substrate and increasing GlcNAc₂ LLO concentrations (0-1000 μ M). Subsequently non-glycosylated (NG) and glycosylated (G) peptides were separated by tricine SDS-PAGE and fluorescence of the tamra-label was detected.

Two distinct protein regions influence LLO specificity of *TbSTT3B* and *TbSTT3C*

TbSTT3B and *TbSTT3C* protein sequences are ~95% identical and sequence differences cluster in three distinct regions (Figure 4) but the OSTs differ significantly with respect to their LLO substrate specificity: *TbSTT3B* does not accept Man₅GlcNAc₂ LLOs, in contrast to *TbSTT3C*. We therefore reasoned that one or a combination of these regions would account for different LLO specificities of *TbSTT3B* and *TbSTT3C*.

Figure 4. Protein sequence alignment of *TbSTT3B* and *TbSTT3C*.

Protein sequences of *TbSTT3B* and *TbSTT3C* were aligned and identical residues are displayed in black. Residues distinct in *TbSTT3B* and *TbSTT3C* were labelled white. The sequences of *TbSTT3B* and *TbSTT3C* show sequence differences in three discrete regions (1-3) labelled by a rectangle. The conserved WWDXG motif is marked by a horizontal line above the sequence.

The differences in LLO specificity led to the inability of *TbSTT3B* to rescue the growth of the $\Delta stt3\Delta alg3$ strain, while *TbSTT3C* was able to complement the *STT3* deletion of this strain. *TbSTT3B-C* chimeras were constructed by exchanging single regions of *TbSTT3B* by corresponding regions of *TbSTT3C* (*TbSTT3B-1C*, *TbSTT3B-2C*, *TbSTT3B-3C*) or by combinations of two regions (*TbSTT3B-1/2C*, *TbSTT3B-2/3C*, *TbSTT3B-1/3C*). To test the effect of the region exchange on LLO specificity, $\Delta stt3\Delta alg3$ cells harbouring the chimeric *TbSTT3B-C* constructs were subjected to 5-FOA induced plasmid shuffling and growth of the cells was assessed (Figure 5A). The exchange of region 1 in *TbSTT3B* strongly reduced growth in the $\Delta stt3\Delta alg3$ ($\text{Man}_5\text{GlcNAc}_2$) and as well in the $\text{Glc}_3\text{Man}_9\text{GlcNAc}_2$ accumulating strain. In contrast, the exchange of region 2 (*TbSTT3B-2C*) allowed cell growth in both backgrounds comparable to *TbSTT3C*. Also the exchange of region 3 (*TbSTT3B-3C*) supported growth of $\Delta stt3\Delta alg3$ cells albeit at a somewhat reduced level. These observations were further substantiated by the *TbSTT3B-C* chimeras with two regions exchanged. Both chimeras containing region 2 (*TbSTT3B-1/2C*, *TbSTT3B-2/3C*) promoted growth similar to *TbSTT3C*, while the chimera with region 1 and 3 (*TbSTT3B-1/3C*) resulted in a severe growth phenotype in $\Delta stt3\Delta alg3$ cells, but not in cells with normal LLO biosynthesis (Figure 5A and 5B). We concluded that region 2 was required to determine LLO substrate specificity of *TbSTT3B* and *TbSTT3C* describing an oligosaccharide recognition domain of this single subunit OST.

Figure 5. LLO specificity of *TbSTT3s* is provided by distinct regions in the proteins.

Strains deleted for genomic *STT3* ($\Delta stt3$) were complemented by a *URA3*-plasmid encoding yeast *STT3* (*ScSTT3*). The strains harboured a second, *LEU2*-marked plasmid encoding *TbSTT3B*, *TbSTT3C*, *TbSTT3B-C* chimeras (see text for description), *ScSTT3* or no *STT3* gene (e.v.). Serial dilutions of (A) $\Delta stt3\Delta alg3$ and (B) $\Delta stt3$ were spotted on 5-FOA containing medium and incubated at 23°C for 7 d ($\Delta stt3$) to 15 d ($\Delta stt3\Delta alg3$) to select for *Ura*⁻ cells. *STT3s* encoded on the *LEU2*-plasmid complementing the genomic $\Delta stt3$ deletion support growth on 5-FOA containing medium. LLO structures of the respective strains were depicted schematically.

***TbSTT3A*, *TbSTT3B* and *TbSTT3C* display differential preferences for peptide substrates**

Having established that region two is responsible for providing specificity towards the LLO donor substrate, we also sought to identify the region(s) of the *TbSTT3* paralogues that provide(s) specificity towards polypeptide substrates. In the first step, differences in the glycosylation efficiencies of the three *TbSTT3* paralogues for different glycosylation sites of yeast membrane proteins were addressed. It was previously reported, that *TbSTT3A* and *TbSTT3C* modified glycosylation sites more efficiently that are located in a sequence context with acidic amino acids while *TbSTT3B* did not display a particular preference for specific amino acids in the local environment of the glycosylation site (Izquierdo et al. 2009). A parallel reaction monitoring (PRM) mass spectrometry (MS)-based method was used to determine the occupancy of glycosylation sites from different yeast membrane proteins, which represents the percentage of peptides modified with a glycan at a given glycosylation site compared to same peptide in wild type cells. To monitor all three *T. brucei* OST proteins, we used the $\Delta stt3\Delta alg9$ yeast strain to compare the glycosylation efficiencies of *TbSTT3A*, *TbSTT3B* and *TbSTT3C*. This strain generates a LLO substrate compatible with all *T. brucei* OSTs and the N-linked glycan is susceptible to EndoH digestion.

The stable isotope labelling with amino acids in cell culture (SILAC) coupled to parallel reaction monitoring (PRM) MS-based technique (Poljak et al.; in preparation) was used to analyse glycosylation occupancy at glycosylation sites on proteins in yeast microsomal membrane preparations. In short, a reference wild type strain was grown in medium containing heavy isotope labelled arginine and lysine while the strains expressing *TbSTT3s* were grown in the corresponding medium using regular amino acids (light). Cells were mixed 1:1, disrupted and samples were enriched for the glycoprotein-rich membrane fraction. N-linked glycans were cleaved by EndoH to maintain the first GlcNAc residue of the glycan on the protein. Proteins were digested enzymatically and the resulting peptides were analysed by liquid chromatography-electro spray-MS/MS. Corresponding light and heavy peptides were paired and site occupancies relative to the reference strain were calculated for *TbSTT3* expressing cells based on light/heavy (L/H) ratios of the peak area values (Supplementary Table 2). Site occupancy reflected the preference of the OST for a given glycosylation site and its local environment. Glycosylation sites that are favoured by a given OST will be glycosylated more efficiently (i.e. higher site occupancy) as compared to sites not located in a favoured peptide sequence context.

Cluster analysis of the site occupancy data acquired for the *TbSTT3* paralogues indicated that *TbSTT3A* and *TbSTT3C* glycosylation efficiency of the 55 analysed sites were similar and the efficiency of glycosylation by *TbSTT3B* was distinct from *TbSTT3A* and *TbSTT3C* (Figure 6A). This result confirmed

previously reported differences in the glycosylation efficiency observed for the *TbSTT3B* and *TbSTT3C* (Izquierdo et al. 2009).

Figure 6. Glycosylation site occupancy and sequence composition analysis for *TbSTT3s* in $\Delta stt3\Delta alg9$ cells.

$\Delta stt3\Delta alg9$ cells complemented with *TbSTT3A*, *TbSTT3B* and *TbSTT3C* were grown in light medium, mixed 1:1 with the wild type reference strain grown in heavy medium and membrane derived peptides were prepared. Peptide abundance was measured by PRM mass spectrometry. Intensity ratios of glycosylated light to heavy peptides were normalized for expression differences in *TbSTT3* expressing cells and wild type cells. The resulting ratios represent the site occupancy for the *TbSTT3* expressing cells relative to the wild type reference strain (reported in %). (A) Site occupancy values for *TbSTT3A*, *TbSTT3B* and *TbSTT3C* were used for cluster analysis. In cluster analysis samples with high similarity are close while samples with low similarity are distant from each other. (B) Sequence composition analysis was performed where amino acids were grouped based on their polarity. Percentage change in respective ratio of each amino acid group between efficiently and poorly glycosylated sequences upstream of glycosylation sequons was calculated for each *TbSTT3* expressing strain. (C) Two sample logo analysis (Vacic et al. 2006) was used to visualize differences between efficiently and poorly glycosylated sequences surrounding the glycosylation sites for each *TbSTT3* expressing strain.

We then examined the polypeptide substrate specificity of *TbSTT3* paralogues in the context of sequence polarity. Sequence composition analysis was performed on glycosylation sequons themselves plus ten residues downstream and upstream of the glycosylation sites. Amino acid residues were grouped based on their polarity into acidic (Asp, Glu), basic (Arg, Lys, His), polar (Ser, Thr, Asn, Glu, Cys, Tyr) and hydrophobic (Ala, Val, Ile, Leu, Met, Phe, Trp, Pro, Gly) group. Sequences were divided into 'efficiently' and 'poorly' glycosylated, when the glycosylation occupancy calculated was more than 85% or less than 25% compared to reference strain, respectively. Ratio of each amino acid group was calculated compared to total number. Percentage change in respective ratios of each amino acid group between efficiently and poorly glycosylated sequences downstream and upstream of glycosylation sequon was calculated for each *TbSTT3* expressing strain. The analysis of sequences downstream of the glycosylation sites showed no apparent difference in sequence specificity between different *TbSTT3* paralogues (Supplementary Table 3). All three enzymes showed preference for hydrophobic residues while polar residues were not favoured. The analysis of upstream sequences revealed that both *TbSTT3A* and *TbSTT3C* preferred acidic residues (Figure 6B). Additionally, both paralogues showed disfavour towards basic residues. However, *TbSTT3B* showed no specific preference for any amino acid type. These results support previously reported difference in the polypeptide acceptor substrate specificity, where *TbSTT3A* and *TbSTT3C* showed selectivity towards glycosylation sequons flanked by acidic residues while *TbSTT3B* lacked any obvious preference (Izquierdo et al. 2009). Furthermore, it has been confirmed that upstream amino acids play a dominant role in *TbSTT3A* acceptor peptide specificity (Jinnelov et al.; personal communication).

Site occupancy data acquired for the *TbSTT3* paralogues was further exploited to examine if there is a particular preference for specific amino acids in the local environment of the glycosylation sites. To establish if there are consensus sequences or patterns that control site-specific N-glycosylation, two sample logo analysis (Vacic et al. 2006) was used to calculate and visualize statistically significant residues surrounding glycosylation sites (Figure 6C). In agreement with sequence composition analysis, both *TbSTT3A* and *TbSTT3C* showed efficient glycosylation of sites containing aspartic acid. Sequences enriched in aspartic acid at -2 position are more likely to be efficiently glycosylated by *TbSTT3A*, while *TbSTT3C* preferred sequences enriched in aspartic acid at -9 position. Similar to previous data, *TbSTT3B* showed no specific preference. Preference for *TbSTT3A* for amino acids immediately adjacent to the glycosylation site has been supported (Jinnelov et al.; personal communication).

A distinct protein region influences polypeptide specificity of *TbSTT3B* and *TbSTT3C*

To define the polypeptide substrate specificity more closely, we used *TbSTT3B*-C chimeras to identify regions of the OST proteins that influenced the preference for certain glycosylation sites. Due to the fact that the chimera *TbSTT3B*-1C yielded poor growth of the strains, we took advantage of the stabilising property of the concomitant exchange of the region 3 and compared the *TbSTT3B*-1/3C (= *TbSTT3C*-2B) to the *TbSTT3B*-2/3C (= *TbSTT3C*-1B) chimera that yielded similar growth in $\Delta stt3\Delta alg9$ cells (Supplementary Figure 2). Glycosylation efficiencies of different chimeras were determined using MS-based method described above and the cluster analysis of the site occupancy data was performed (Figure 7A). *TbSTT3B*-1/3C displayed highest similarity with *TbSTT3C* while the corresponding chimera *TbSTT3B*-2/3C showed only little similarity with *TbSTT3C*. Exchange of region 1 seems to influence glycosylation efficiency of the two *TbSTT3* paralogues examined.

We defined this specificity more closely and focused the analysis only on the sites that were differentially glycosylated by *TbSTT3B* and *TbSTT3C*. Sequence composition analysis was performed where the percentage change in respective ratios of acidic and basic amino acid groups between efficiently and poorly glycosylated sequences upstream of glycosylation sequon was calculated for each *TbSTT3* expressing strain. As expected, *TbSTT3C* showed preference for the acidic residues while, in this analysis, these were disfavoured by *TbSTT3B* enzyme (Figure 7B). Similar to *TbSTT3C*, *TbSTT3B*-1/3C chimera displayed preference for acidic sequences upstream of glycosylation sites. Interestingly, two sample logo analysis revealed that both *TbSTT3C* paralogue and *TbSTT3B*-1/3C chimera showed preference for an aspartic acid at the same position upstream of the glycosylation sequon (Figure 7C). Similar to previous data, *TbSTT3B* showed no specific preference and the same was true for *TbSTT3B*-2/3C chimera. Involvement of region 1 in sequon specificity of *TbSTT3B* and *TbSTT3C* has been demonstrated before where upon genetic rearrangements a chimeric gene was generated containing the first variable region of *TbSTT3C* flanked by *TbSTT3B* sequences. The chimeric *TbSTT3B*/C/B protein described in this publication showed much less efficient recognition of the native substrate of *TbSTT3B* while it appeared to have attained a peptide acceptor specificity more similar to *TbSTT3A* than *TbSTT3B* (Castillo-Acosta et al. 2013).

Figure 7. Glycosylation site occupancy and sequence composition analysis for *TbSTT3B-1/3C* and *TbSTT3B-2/3C* chimeras in $\Delta stt3\Delta alg9$ cells.

$\Delta stt3\Delta alg9$ cells complemented with *TbSTT3B*, *TbSTT3C*, *TbSTT3B-1/3C* and *TbSTT3B-2/3C* were grown in light medium, mixed 1:1 with the wild type reference strain grown in heavy medium and membrane derived peptides were prepared. Intensity ratios of glycosylated light to heavy peptides were normalized for expression differences in *TbSTT3* expressing cells and wild type cells. The resulting ratios represent the site occupancy for the *TbSTT3* expressing cells relative to the wild type reference strain (reported in %). (A) Site occupancy values for *TbSTT3B*, *TbSTT3C*, *TbSTT3B-1/3C* and *TbSTT3B-2/3C* were used for cluster analysis. In cluster analysis samples with high similarity are close while samples with low similarity are distant from each other. (B) Sequence composition analysis was performed where amino acids were grouped based on their polarity. Percentage change in respective ratio of each amino acid group between efficiently and poorly glycosylated sequences upstream of glycosylation sequon was calculated for each *TbSTT3* expressing strain. (C) Two sample logo analysis (Vacic et al. 2006) was used to visualize differences between efficiently and poorly glycosylated sequences surrounding the glycosylation sites for each *TbSTT3* expressing strain.

Discussion

Functional expression of single subunit OSTs from kinetoplastids in *Saccharomyces cerevisiae* has proven to be a useful model system to study the properties of STT3s from *L. major*, *T. cruzi* and *T. brucei* (Castro et al. 2006; Parsaie Nasab et al. 2008; Hese et al. 2009; Izquierdo et al. 2009). Yeast genetics methods allow manipulations of the LLO biosynthesis pathway to generate specific intermediate oligosaccharide structures (Jakob et al. 1998) that can be used to study the influence of altered LLO substrates on OSTs. Consequences of such altered substrates for N-glycosylation can be monitored by analysing N-glycoproteins, the products of the OST catalysed reaction. Both single N-glycoproteins like carboxypeptidase Y (te Heesen et al. 1992; Helenius et al. 2002) and MS-based methods, which allow a broader view on many N-glycoproteins at the same time, were used to study consequences of alterations in the N-glycosylation process (Poljak et al; in preparation). Furthermore, the structures of glycans transferred to proteins can be identified and characterised to gain insights into OST selectivity, ALG glycosyltransferase products or processing of protein bound glycans (Jakob et al. 1998; Cipollo and Trimble 2002; Kelleher et al. 2007). The combination of genetics and analytical tools available in *S. cerevisiae* thus represents an excellent system to perform reverse genetics approaches to study particular OST features.

In vivo analysis of the *T. brucei* VSG221 protein showed that *TbSTT3A* transfers $\text{Man}_5\text{GlcNAc}_2$ glycans to protein, while *TbSTT3B* prefers $\text{Man}_9\text{GlcNAc}_2$ as substrate for N-glycosylation (Izquierdo et al. 2009). Analysis of VSG221 proteins in *T. brucei* *TbALG3*^{-/-} and *TbALG12*^{-/-} mutant strains revealed that also LLO intermediates can serve as substrates for both *TbSTT3A* and *TbSTT3B*, although with reduced efficiency. It was hypothesised that efficient glycosylation of VSG221 by *TbSTT3A* correlates with the absence of the LLO c-branch, while for *TbSTT3B* the presence of the c-branch is an important determinant to improve glycosylation (Manthri et al. 2008; Izquierdo et al. 2012).

Analysis of the LLO specificities of *TbSTT3A* and *TbSTT3B* in *T. brucei* was possible, since the two VSG221 glycosylation sites get selectively modified either by *TbSTT3A* with $\text{Man}_5\text{GlcNAc}_2$ glycans or by *TbSTT3B* with $\text{Man}_9\text{GlcNAc}_2$ oligosaccharides. This selectivity for a specific glycosylation sequon is provided by the distinct polypeptide specificities of *TbSTT3A* and *TbSTT3B* (Izquierdo et al. 2009). Since *TbSTT3C* was not expressed in *T. brucei*, its substrate specificity was investigated in the heterologous yeast expression system. *TbSTT3C* shared the preference for acidic sequons with *TbSTT3A* but used $\text{Man}_9\text{GlcNAc}_2$ as LLO substrate, as observed with *TbSTT3B* (Izquierdo et al. 2009).

Our detailed investigations on LLO specificity in the yeast *in vivo* system confirmed the results obtained from *T. brucei* for *TbSTT3A* and *TbSTT3B*. Furthermore, we could demonstrate that the inability of *TbSTT3A* to complement the *STT3* deletion of yeast cells was independent of LLO glucosylation. Since

terminal Glc residues of the LLO a-branch did not influence *TbSTT3A*, although *T. brucei* synthesises only non-glycosylated LLOs (Samuelson et al. 2005), an interaction of *TbSTT3A* with the terminal Man residue of the LLO a-branch seems unlikely. The inability of *TbSTT3A* to support growth of the $\Delta stt3$ and $\Delta stt3\Delta alg6$ strains was rather due to the presence of LLO c-branch mannoses which seemed to prevent efficient glycosylation by *TbSTT3A*. *TbSTT3B* was able to support growth of all strains tested with the exception of $\Delta stt3\Delta alg3$. In *T. brucei*, *TbSTT3B* modified VSG221 in a *TbALG3*^{-/-} strain, although with reduced efficiency (Manthri et al. 2008). The inability of *TbSTT3B* to rescue the growth of $\Delta stt3\Delta alg3$ yeast cells was therefore likely to result from reduced overall glycosylation levels, which were too low to allow survival of the yeast cells, rather than the inability to use Man₅GlcNAc₂ LLOs as substrate in the heterologous host. Opposed to *TbSTT3A* and *TbSTT3B*, which both displayed distinct LLO donor substrate preferences, *TbSTT3C* did not show a specific preference towards the LLO donor substrates tested. It can be speculated that *TbSTT3C* does not recognise or only weakly interact with the Man residues added to the LLO substrate in the ER. Instead *TbSTT3C* may be recognising only a core structure of the LLO that is recognised by all three *TbSTT3* paralogues. Although *TbSTT3* paralogues could utilise a range of LLO substrates to glycosylate proteins, no intermediate glycan structures are transferred to protein by *TbSTT3A* and *TbSTT3B* unless *ALG* mutations were introduced (Manthri et al. 2008; Izquierdo et al. 2009; Izquierdo et al. 2012). This indicates, that additional factors like availability or accessibility of LLO biosynthesis intermediate and k_m values of the *ALG* enzymes fine tune the glycosylation machinery leading to the specific transfer of Man₅GlcNAc₂ LLOs by *TbSTT3A* and Man₉GlcNAc₂ oligosaccharides by *TbSTT3B* (Izquierdo et al. 2009).

We could demonstrate transfer of a GlcNAc₂ glycans by all *T. brucei* OSTs to substrate peptides. This had several implications: 1) *TbSTT3* paralogues recognise the GlcNAc₂ core of LLO substrates 2) *T. brucei* OSTs distinguish LLOs by distal Man residues, probably of the c-branch, since the apparent k_m values of all three *TbSTT3* paralogues for the GlcNAc₂ substrate were similar. 3) *TbSTT3* enzymes are not highly specific for the length of the lipid carrier; although the natural lipid carrier of *T. brucei* has 11-12 isoprene units (Low et al. 1991), both truncated (five isoprene units) and elongated lipid carriers (15-16 isoprene units) (Jung and Tanner 1973; Adair and Cafmeyer 1987) were accepted as LLO substrates *in vitro* and *in vivo*, respectively. Unlike *T. brucei* OSTs, *S. cerevisiae* OST was shown to only efficiently use GlcNAc₂ as LLO substrate *in vitro* when dolichol but not truncated lipid carrier moieties were used (Fang et al. 1995; Tai and Imperiali 2001). This may hint towards differences between yeast OST and *TbSTT3*s with regards to the requirements for the lipid-portion of the LLO substrate. One might speculate that the specificity for the lipid moiety of LLOs in yeast may be provided by a non-catalytic OST subunit.

The heterologous expression system allowed us to perform targeted structure-function analyses. Region 2, which was found to be important for LLO specificity, is located in the C-terminal part of the *TbSTT3* protein after the last predicted transmembrane helix. This C-terminal domain was predicted to be localised in the ER lumen due to the presence of the highly conserved WWDXXG motif that is important for the glycosylation reaction of OSTs (Yan and Lennarz 2002; Igura et al. 2008; Lizak et al. 2011). The results presented here identify for the first time regions of the *TbSTT3* proteins that are important for LLO specificity and provide a basis to further investigate the molecular mechanisms and contribution of single amino acids in OST LLO interaction.

Glycosylation efficiency of a given OST can be determined by analysing site occupancy for different substrate polypeptides (Parsaie Nasab et al. 2008; Izquierdo et al. 2009; Schulz and Aebi 2009; Xu et al. 2015; Zacchi and Schulz 2016; Poljak et al. in preparation). Here we compared the site occupancies for the three *TbSTT3* paralogues in the $\Delta stt3\Delta alg9$ strain relative to a wild type reference strain. Our results confirmed previous observations, made in two different expression hosts, that *TbSTT3A* and *TbSTT3C* have similar polypeptide substrate preferences (Izquierdo et al. 2009). We further found, that region 1 influences the glycosylation efficiency of certain polypeptide substrate glycosylation sites. *PglB*, the bacterial homologue of *STT3*, interacts with the threonine/serine residue of the glycosylation sequon of its peptide substrate via residues of the conserved WWDXXG motif, which determines the specificity for the sequon sequence. A periplasmic loop connecting transmembrane helices 9 and 10 (i.e. external loop 5; EL5) also showed significant interaction with the peptide substrate. The C-terminal part of EL5 pins the peptide against the periplasmic domain, but it also contains the conserved residue E319 that is part of the catalytic site of *PglB* (Lizak et al. 2011). In the *TbSTT3* paralogues, the region surrounding the WWDXXG motif is completely conserved. Therefore, it seems unlikely that this region is responsible for the differences observed in site occupancy between *TbSTT3B* and *TbSTT3C*. Sequence alignments between *PglB* from *Campylobacter lari* and *TbSTT3B* and *TbSTT3C* showed that the conserved residue E319 of *PglB* has an equivalent glutamic acid residue in the *TbSTT3s* that is located in region 1 of *TbSTT3B* and *TbSTT3C* (i.e. E396). Hence, it is tempting to speculate that region 1 could be the functional equivalent to the EL5 described in *PglB*. Region 1 might interact with polypeptide substrates and modulate the glycosylation efficiency of *TbSTT3s*. Interestingly, towards the C-terminal end of region one, both *TbSTT3A* and *TbSTT3C* have conserved sequences, while the amino acid residues of *TbSTT3B* at these positions are different. This seemed to coincide with the observed differences in site occupancy and sequence composition for *TbSTT3A* and *TbSTT3C* compared to *TbSTT3B*. We showed that amino acids upstream of glycosylation site play a dominant role in *TbSTT3s* polypeptide specificity. Furthermore, we were able to depict specific amino acid residues in polypeptide substrate sequences that increase the chances of such substrates being

efficiently glycosylated by different *TbSTT3* paralogues. Sequences enriched in aspartic acid at -2 position are more likely to be efficiently glycosylated by *TbSTT3A*, while *TbSTT3C* preferred sequences enriched for aspartic acid at -9 position. We also showed that sequence preference for a specific amino acid is region 1 dependent. More experimental work and crystal structures of eukaryotic single protein OSTs will provide insights into the molecular basis of polypeptide specificity.

Materials and Methods

Media, Yeast strains and plasmids

Standard yeast media and molecular biology methods were used (Guthrie and Fink 1991). For maintenance of plasmids, cells were grown in appropriate synthetic medium lacking amino acids necessary for selection.

To generate haploid double mutant strains with genomic deletions of *STT3* and *ALG3*, *ALG9*, *ALG6* genes to test the complementation by different *TbSTT3*s, haploid mutant strains with deletions in *ALG3*, *ALG6* and *ALG9* genes were purchased (Euroscarf): Y13108 (*alg3Δ::KanMX4*), Y01993 (*alg9Δ::KanMX4*) and Y11778 (*alg6Δ::KanMX4*). These strains were individually mated with YBS10 and YBS11 strains, respectively (Parsaie Nasab et al. 2008), sporulation was induced and tetrads were dissected on YPD plates containing 1 M sorbitol. Haploid spores harbouring the *STT3*-plasmid and the two deletions in the *STT3* and *ALG3*, *ALG6* or *ALG9* loci were identified on G418-containing media in nonparental ditype tetrads. The absence of the *ALG3*, *ALG6* and *ALG9* genes in the double mutant strains was confirmed by PCR. The $\Delta stt3\Delta alg12$ strain was generated from YG2082 by exchanging *LmSTT3D* by the plasmid encoding the yeast *STT3* locus (Zufferey et al. 1995; Parsaie Nasab et al. 2008).

To test complementation of the *STT3* deletion by *TbSTT3* paralogues the following strains were used: $\Delta stt3$ (YBS11) (*STT3::kanMX4 MATa his3Δ1 leu2Δ0 met15Δ0 ura3Δ0 lys2Δ0*) (Parsaie Nasab et al. 2008); $\Delta stt3\Delta alg6$ (*stt3Δ::kanMX4 alg6Δ::kanMX4 MATa his3Δ1 leu2Δ0 met15Δ0 ura3Δ0 lys2Δ0*); $\Delta stt3\Delta alg12$ (*stt3Δ::kanMX4 alg12Δ::kanMX4 MATa his3Δ1 leu2Δ0 met15Δ0 ura3Δ0 lys2Δ0*); $\Delta stt3\Delta alg9$ (*stt3Δ::kanMX4 alg9Δ::kanMX4 MATa his3Δ1 leu2Δ0 met15Δ0 ura3Δ0 lys2Δ0*); $\Delta stt3\Delta alg3$ (*stt3Δ::kanMX4 alg3Δ::kanMX4 MATa his3Δ1 leu2Δ0 ura3Δ0 lys2Δ0*). The *STT3* deletion was complemented by a plasmid encoding the yeast *STT3* locus encoding the yeast *STT3* locus in a URA3 marked YEp352 vector (Zufferey et al. 1995). These cells were transformed with *T. brucei* *STT3* paralogues encoded by LEU2 marked plasmids under the control of the yeast GPD promoter (Izquierdo et al. 2009). The yeast *STT3* locus was cloned as a *Hind III* fragment from the yeast *STT3* locus harbouring plasmid (Zufferey et al. 1995) into the pRS425GPD vector as control for the plasmid shuffling procedure. Cells were grown after plasmid shuffling in appropriate defined medium containing 1 M sorbitol.

TbSTT3B-C chimera plasmids were generated by homologous recombination. PCR fragments encoding the different regions (1, 2, 3) were generated with primers 5'-AGCGCAACTACAGAGAAC-3', 5'-ACAGATGGCAAGGACAAC-3', 5'-CGTTCCTGCTGTTGTAATC-3', 5'-GCTATGTGCTCGTGATTCC-3', 5'-CTGAAGATGCCCGTATTCTC-3' and 5'-CGCACGATAATAAGCGTCAC-3' using either *TbSTT3B* or *TbSTT3C*

plasmids as template. PCR fragments were designed to have overlapping sequences with the vector or a PCR fragment containing a neighbouring region. To assemble the different chimeras, *TbSTT3B* vector was gapped with *Nco* I and *Bgl* II and yeast cells were co-transformed with the gapped vector and all possible combinations of PCR fragments encoding for the 3 different regions from either *TbSTT3B* or *TbSTT3C* for homologous recombination. Plasmids were isolated from yeast, amplified in *E. coli* DH5 α and correct chimera assembly was confirmed by sequencing the inserted DNA. For overexpression of *ALG12*, previously described constructs were used (Burda et al. 1999). Analysis of glycosylation site occupancy was performed with three biological replicates of the Δ *stt3* Δ *alg9* strain harbouring *TbSTT3A*, *TbSTT3B*, *TbSTT3C* or *TbSTT3B-C* chimera plasmids. KP4 (MAT α *his3* Δ 1 *leu2* Δ 0 *lys2* Δ 0 *ura3* Δ 0 *arg4* Δ ::0) was used as reference strain.

Specificity for lipid linked oligosaccharides

Lipid-linked oligosaccharide specificity was tested by plasmid shuffling with the respective Δ *stt3* Δ *alg*-double mutant strains harbouring both, the *URA3* marked *pScSTT3* plasmid and the *LEU2* marked *TbSTT3* or *ScSTT3* encoding plasmids. These cells were subjected as serial dilution to minimal medium containing 1 mg/ml 5-fluoroorotic acid (5-FOA (Boeke et al. 1987)) and 1 M sorbitol. The presence of 5-FOA allowed the selection of cells that lost the Ura⁺ *pScSTT3* plasmid. These Ura⁻ cells only survived when the *STT3* genes encoded on the *LEU2*-plasmid could complement the yeast *STT3* deletion. Strains were incubated at 23°C for 7-15 d depending on cell growth.

In vitro glycosylation assay

ScSTT3, *TbSTT3B* and *TbSTT3C* were expressed in Δ *stt3* cells and *TbSTT3A* was expressed in Δ *stt3* Δ *alg3* cells. Cells were grown to log-phase (OD_{600nm} 2-3), harvested by centrifugation and washed in ice-cold PBS. Cells were resuspended in lysis buffer (PBS (pH7.3); 1 mM DTT; complete protease inhibitor cocktail (PIC; Roche); 10 mM PMSF) and broken with glass beads at 4°C. The lysate was centrifuged (17211 x g, 10 min, 4°C) and the supernatant was subjected to ultracentrifugation (202875 x g, 1 h, 4°C). Pellets were homogenized in resuspension buffer (PBS (pH 7.3); 5% (v/v) glycerol; 5 mM PMSF; PIC) to yield a final concentration of 1 μ g pellet material per ml. Resuspended microsomes were used for *in vitro* assays.

The *in vitro* assay method was adapted from (Kohda et al. 2007) and was conducted in reaction buffer (10 mM TrisCl (pH 7.3); 1 mM DTT; 1 mM MnCl₂) with 20 μ M N-terminally tamra-labeled DANYTK peptide substrate (JPT peptide technologies), varying concentrations of chemically synthesized GlcNAc₂ LLO substrate (Robert Woodward) and homogenized microsomes. To show cation

dependency of the glycosylation reaction 1 mM EDTA was added to the reaction mixture. Reactions were incubated at 28°C for 10-12 h. After incubation, samples were mixed with reducing sample buffer 7:3 (v/v) (225 μ M TrisCl (pH 6.8); 50% (v/v) glycerol; 5% (w/v) SDS; 0.05% (w/v) bromophenol blue; 25 μ M DTT), incubated at 95°C for 5 min and analysed by tricine-SDS-PAGE (Schagger 2006). Fluorescence of the tamra-labeled peptide was detected in gel with a FX Imager Pro Plus (BioRad) scanner. Fluorescence intensities of bands were analysed by ImageJ software and values were used to estimate the degree of conversion from non-glycosylated to glycosylated form of the peptide. These values were used for a determination of the k_{mapp} range.

Analysis of N-linked oligosaccharides

Yeast cells were grown to early logarithmic phase ($OD_{600\text{nm}} = 0.8-1.2$) and 50 OD of cells (5×10^8 cells) were harvested by centrifugation, washed with ice-cold water and resuspended in 200 μ l of ice-cold water. 25 μ l of TCA (100% (w/v)) were added to the cell suspension. After incubation on ice for 3 min, the precipitate was washed twice with ice-cold acetone and dried at 50°C for 10 min. Pellets were resuspended in 200 μ l S-buffer (50 mM sodium-phosphate buffer (pH 7.5), 0.4% SDS, 40 mM DTT) and vortexed with maximum speed at 50°C for 1 h with glass beads. The slurry was extracted with 3 x 250 μ l S-buffer and cleared by centrifugation. 500 μ l supernatant were mixed with 55 μ l iodoacetamide (0.5 M) and incubated for 15 min at 37°C. 62 μ l NP-40 (10% (v/v)) and 69 μ l sodium-phosphate buffer (0.5 M, pH 7.5) were added. Glycans were released by addition of 1 μ l of peptide: N-glycosidase F (PNGaseF; New England Biolabs) and incubation at 37°C for 16 h. For the clean-up of released glycans prepacked C 18 Sep Pak columns (Waters) which were connected to columns (extended volume empty reservoirs; Socochem SA) packed with Supelclean ENVI-Carb 120/400 (Sigma-Aldrich) were used. The combined columns were equilibrated with methanol, acetonitrile (ACN), ACN/H₂O (50:50 (v/v)), and ACN/H₂O (2:98 (v/v)). Samples were applied onto the columns after supplementation with ACN/H₂O (2:98 (v/v) final concentration). Columns were washed with ACN/H₂O (2:98 (v/v)), and glycans were eluted from the ENVI-Carb column with ACN/H₂O (25:75 (v/v)). The solvent was evaporated in a speed vacuum. Purified NLOs were fluorescently labelled with 2-aminobenzamide (2-AB) by incubation in 25 μ l of labelling solution (70% (v/v) DMSO; 30% (v/v) glacial acetic acid; 0.35 M sodium cyanoborohydride (Fluka); 1 M 2-AB (Sigma)) at 65°C for 2 h. Labelled NLOs were purified with paper columns. 4 filter paper disks were placed in a 1 ml syringe were washed with 2 x 1 ml acetic acid (30% (v/v)) and twice with 1 ml of water. The filter paper was equilibrated with 2 x 1 ml ACN and 2 x 1 ml ACN/H₂O (95:5 (v/v)). Samples were cooled down and ACN was added (final concentration 95% (v/v)). Samples were added to filter paper and washed with 8 x 1 ml ACN/H₂O (95:5 (v/v)). Glycans were eluted with 2 x 50 μ l deionized water. Subsequently, ACN was added to samples (final concentration

70% (v/v)) and samples were filtered with 0.45 μm filter spin columns (Millipore). HPLC analysis of the samples was performed using a normal-phase column (Supelcosil LC-NH₂, 250 x 4.6 mm; Sigma-Aldrich) and a Supelcosil LC-NH₂ Supelguard Cartridge (Sigma-Aldrich). A linear gradient ranging from ACN 70% (v/v) to 55% (v/v) ACN over 75 min (flowrate: 0.8 ml/min) was used to separate NLOs. Fluorescence of 2-AB labelled NLOs was detected using excitation at 330 nm and detection of the emission at 420 nm. NLO peaks were assigned based on retention time of a NLO standard ranging from Man₅GlcNAc₂ to Man₉GlcNAc₂ isolated from RNase B (Sigma). Peak areas were calculated with Chromeleon Software (Dionex).

Sample preparation for mass spectrometry

Cells were grown at 25°C in synthetic complete medium (0.67% (w/v) yeast nitrogen base, 2% (w/v) glucose with appropriate amino acid supplements) containing either 20 mg/l light [¹²C₆/¹⁴N₂] L-lysine and [¹²C₆] L-arginine or heavy [¹³C₆/¹⁵N₂] L-lysine and [¹³C₆] L-arginine (Cambridge Isotope laboratories). Cells were harvested in early log phase (OD_{600nm} = 0.8-1.2) by centrifugation and mixed 1:1 (w/w) for membrane protein preparation.

Membrane proteins were prepared as described (Mueller et al. 2015). Shortly, cells were lysed and microsomal fractions were collected by high spin centrifugation at 16,000xg, 4°C for 20 min. Proteins were processed using the filter-assisted sample preparation (FASP) protocol (Wisniewski et al., 2009). After reduction and alkylation, proteins were digested with Lys-C (20 $\mu\text{g}/\text{ml}$; Wako Pure Chemical, Richmond, VA) and trypsin (20 $\mu\text{g}/\text{ml}$; Promega) endopeptidases. Protein digestion was directly followed by EndoH (500 U; New England BioLabs) endoglycosidase treatment. Peptides were desalted using C18 ZipTips (Millipore) and dried using speed vacuum. Desalted peptides were resuspended in ACN/H₂O (3:97 (v/v)) with formic acid (FA; 0.1% (v/v)) and analysed by LC-ESI-MS/MS.

Mass Spectrometry analysis

MS analysis was performed by LC-ESI-MS/MS in parallel reaction monitoring (PRM) mode using a Q Exactive HF instrument (Thermo Scientific) coupled to ACQUITY UPLC system (Waters). Peptides were separated on HSS T3 column (78 μm x 150 mm, 1.8 μm) packed with C18 material (Waters). Peptides were eluted using the gradient of 2 - 35% solvent B (99% (v/v) ACN, 0.1% (v/v) FA) over 90 min at a flow rate of 0.3 $\mu\text{l}/\text{min}$. All samples were analysed using two PRM methods at an Orbitrap resolution of 30 000 or 60 000, based on scheduled inclusion lists containing the 175 and 128 target precursor ions, respectively, including retention time iRT standard peptides (Biognosys) (Appendix Table 1). The full scan event was collected using a m/z 50–1400 mass selection, an Orbitrap resolution of 60 000 (at

m/z 400), target automatic gain control (AGC) value of 3×10^6 and a maximum injection time of 30 ms. The PRM scan events used an Orbitrap resolution of 30 000 or 60 000, maximum fill time of 30 or 110 ms respectively, an AGC value of 1×10^6 and with an isolation width of 2 m/z. Fragmentation was performed with a normalized collision energy of 28 and MS/MS scans were acquired with a starting mass of m/z 150. Scan windows were set to 10 min for each peptide in the final PRM method to ensure the measurement of 6–10 points per LC peak per transition.

Data processing and analysis

Skyline software (v2.6.0) with standard settings was used for data processing (MacLean et al. 2010). Briefly, raw MS data files were imported and the peaks were manually inspected and adjusted to ensure proper peak picking and peak integration. The resulting light to heavy intensity ratio (L/H) for glyco-peptides modified with HexNAc was used to calculate the relative site occupancy for the given peptide/ glycosylation site. The relative site occupancy was normalized for expression differences between heavy labelled reference wild type strain (H) and the *TbSTT3* expressing light strains (L) by dividing the L/H intensity ratio for the occupied glyco-peptide by the median of L/H intensity ratios reported for all non-glyco (i.e. not containing a NxT/S sequon) peptides from the same protein as the glyco peptide.

Cluster analysis was performed with Cluster 3.0 software (library version 1.50) (Eisen et al. 1998; de Hoon et al. 2004) using the Spearman rank correlation to calculate similarity between site occupancy data for different *TbSTT3*s. Hierarchical clustering with the single linkage method was used to generate a dendrogram visualized with Java TreeView 1.1.6 software.

Chapter 3b

Supplementary Information to Chapter 3

Supplementary Figure 1. Test of *in vitro* activity with *TbSTT3* paralogues.

(A) Structure of the pentaprenyl-pyrophosphate-GlcNAc₂ LLO used for *in vitro* assays (B) Detergent free microsomes were prepared from yeast cells with deletion of endogenous *STT3* and expressing *TbSTT3A*, *TbSTT3B* or *TbSTT3C*. Microsomes, tamra-labelled DANYTK peptide substrate and GlcNAc₂ LLO substrate were added to (+) or omitted (-) from the reaction mixture. EDTA was added to test metal ion dependence of the reaction. Glycosylated (G) and non-glycosylated (NG) peptides were separated by tricine SDS PAGE and fluorescence of the tamra label was detected. (C) Microsomes prepared from yeast cells with functional endogenous OST were incubated with tamra-labelled DANYTK peptide and increasing concentrations of GlcNAc₂ LLO substrate to test activity of *S. cerevisiae* OST (*ScOST*) towards the LLO substrate. Glycosylated (G) and non-glycosylated (NG) peptides were separated by tricine SDS PAGE and fluorescence of the tamra label was detected.

Supplementary Figure 2. Growth phenotypes of $\Delta stt3\Delta alg9$ cells expressing *TbSTT3B-C* chimeras.

$\Delta stt3\Delta alg9$ complemented by *ScSTT3*, *TbSTT3B*, *TbSTT3C*, or the *TbSTT3B-C* chimeras (*TbSTT3B-1C*, *TbSTT3B-1/3C*, *TbSTT3B-2/3C*) were grown in medium selecting for the plasmid and containing 1 M sorbitol. Serial dilutions of the cultures were spotted on selective medium containing 1 M sorbitol and cells were incubated for 4 d at 23°C.

Supplementary Table 1. Relative peak areas of protein linked oligosaccharides isolated from $\Delta stt3\Delta alg9$ cell expressing *ScSTT3*, *TbSTT3A*, *TbSTT3B* or *TbSTT3C* and harbouring additionally e.v. or *pALG12*.

Values represent percentage of individual peak areas ($\text{Man}_6\text{GlcNAc}_2$ (Man6)- $\text{Man}_{11}\text{GlcNAc}_2$ (Man11)) relative to the total peak area of all peaks (Man6-Man11). Values are average values of three individual experiments and standard deviation is indicated by \pm values.

Supplementary Table 2. Glycosylation site occupancy values for *Δstt3Δalg9* cells complemented with *TbSTT3A*, *TbSTT3B*, and *TbSTT3C* relative to yeast OST from the wild type reference strain.

Values represent the median of three biological replicates and are expressed as % glycosylation relative to ScOST.

Supplementary Table 3. Analysis of sequence preference of different TbSTT3 paralougues, analysed on glycosylation sequons themselves plus ten residues downstream and upstream. Amino acid residues were grouped based on their polarity into acidic (Asp, Glu), basic (Arg, Lys, His), polar (Ser, Thr, Asn, Glu, Cys, Tyr) and hydrophobic (Ala, Val, Ile, Leu, Met, Phe, Trp, Pro, Gly) group. Sequences were divided into 'efficiently' and 'poorly' glycosylated, when the glycosylation occupancy calculated was more than 85% or less than 25% compared to reference strain, respectively. Values represent the number of amino acids present in each group and the percentage compared to the overall number. Percentage difference is calculated by subtracting percentage in efficient to poor sequences.

Chapter 4

Functional Characterization of the Essential Oligosaccharyltransferase Subunit WBP1 in Yeast

Summary

Oligosaccharyltransferase (OST) is an enzyme responsible for N-linked glycosylation, a highly conserved and an essential protein modification that generates a huge diversity of glycoproteins with distinct cellular functions. Yeast OST is a multi-subunit complex composed of nine proteins, where the Wbp1 is an essential glycoprotein whose function within the complex is not known. In order to elucidate the role of Wbp1, we used a reverse genetics strategy to target conserved residues for site directed mutagenesis on the chromosomal level in yeast cells. The effect of the mutations on the OST activity was investigated by examining the OST complex stability and N-glycosylation efficiency *in vivo*. Complex stability analysis was performed by monitoring turnover rates and steady state levels of OST subunits. Glycosylation efficiency was determined by immunoblot analysis. We have identified novel *wbp1* mutants that affect OST activity through complex destabilization, either as a result of Wbp1p destabilization itself or due to impaired interaction with subcomplex partner subunits.

Introduction

N-linked protein glycosylation is an essential and highly conserved process carried out on the ER membrane in eukaryotes. In fungi, plants and mammals the pathway involves the assembly of an oligosaccharide consisting of two N-acetylglucosamine (GlcNAc), nine mannoses (Man) and three glucoses (Glc) on a lipid carrier dolichol (Dol), which is then transferred *en bloc* by the oligosaccharyltransferase (OST) enzyme. The ALG (asparagine-linked glycosylation) genes encode glycosyltransferases involved in sequential addition of sugar residues to the dolichol phosphate (Dol-P). Oligosaccharide assembly starts at the cytoplasmic side of the ER membrane, where the cytoplasmic ALG enzymes involved use nucleotide activated sugar donors (UDP-GlcNAc and GDP-Man). The first GlcNAc residue is added to the Dol-P to form Dol-PP-GlcNAc, followed by the subsequent addition of one GlcNAc and five Man residues resulting in Dol-PP-GlcNAc₂Man₅ oligosaccharide. The lipid-linked oligosaccharide (LLO) is then flipped towards the ER lumenal side (Breitling & Aebi 2013). The flipping process is not yet fully understood, although it has been proposed to require Rft1p (Helenius et al. 2002). The ALG enzymes acting in the ER lumen utilize lipid-linked donors (Dol-P-Man and Dol-P-Glc) and are responsible for the addition of four Man and three Glc residues resulting in the mature Dol-PP-GlcNAc₂Man₉Glc₃ LLO (Breitling & Aebi 2013). Lower eukaryotes synthesize truncated LLO structures ranging from GlcNAc₂Man₉ in *Leishmania major* to the extreme GlcNAc₂ in *Girardia lamblia* (Samuelson et al. 2005). The bipartite biosynthesis of the LLO and high substrate specificity for the defined LLO intermediates makes the process extremely ordered. Therefore, disruption of ALG genes acting in the lumenal LLO assembly results in the accumulation of specific LLO intermediates allowing for the analysis of the suboptimal LLO substrate effect on OST glycosylation efficiency.

Fully assembled glycan is transferred by the central enzyme, OST to an asparagine residue located within highly conserved N-X-S/T sequon (X = any amino acid except proline) of a polypeptide chain. *Saccharomyces cerevisiae* OST is a hetero-oligomeric membrane complex composed of essential subunits encoded by *STT3*, *WBP1*, *OST1*, *OST2* and *SWP1* and the non-essential genes *OST3*, *OST6*, *OST4* and *OST5*, existing in two isoforms containing either Ost3p or Ost6p (Kelleher & Gilmore 2006). Yeast and mammalian OST subunits are homologous: STT3A and STT3B (STT3), OST48 (WBP1), ribophorin I (OST1), ribophorin II (SWP1), N33/Tusc3 and IAP (OST3 and OST6) as well as OST4 (OST4). Mammalian OST was suggested to contain two additional subunits KCP1 and DC2 (Wilson et al. 2011). Some eukaryotes contain only some of the OST subunits found in hetero-oligomeric complex. Hetero-tetrameric OST complexes were described in *Trichomonas vaginalis*, *Entamoeba histolytica* and *Plasmodium falciparum* genomes where homologues of Ost1p, Ost2p, Stt3p and Wbp1p were identified while *Cryptosporidium parvum* contains all the subunits except Swp1p and Ost5p (Kelleher

& Gilmore 2006). One inherent feature to all OST subunits is integration into the complex and interaction with other subunits. Many experiments led to the identification of three subcomplexes formed by Stt3p-Ost4-Ost3/6, Wbp1-Ost2-Swp1p and Ost1-Ost5 (S te Heesen et al. 1993; Silberstein 1995; Fu et al. 1997; Karaoglu et al. 1997; Reiss, te Heesen, Gilmore, Zufferey, Aebi, et al. 1997; Yan et al. 2003). A novel model for OST complex assembly has been proposed where Wbp1p, Ost2 and Swp1p form one subcomplex; Ost1p is first stabilized by Ost5p and then is involved in the formation of the second subcomplex with Stt3p. The two subcomplexes, together with Ost4p, form a bigger subcomplex while Ost4p then anchors Ost3/6p into the final complex (Mueller et al. 2015). Thus, the essential function of the OST subunits in complex stability has to be taken into account when reverse genetic tools are used for functional investigations.

STT3 encodes the catalytic subunit of OST (Yan & Lennarz 2002; Daniel J. Kelleher et al. 2003; Nilsson et al. 2003). Some protozoan, archaeal and bacterial species contain single subunit OSTs, corresponding to eukaryotic STT3 subunit (Wacker 2002; Nasab, Benjamin L Schulz, et al. 2008; Hese et al. 2009; Izquierdo et al. 2009). Some of these (such as *Leishmania major* single subunit OST, *LmSTT3*) are capable of complimenting the loss of yeast STT3 subunit (Nasab, Benjamin L Schulz, et al. 2008; Hese et al. 2009). Thus, cells with a non-functional yeast OST are viable in the presence of *LmSTT3D* protein. Given the fact that a single subunit OST can compensate the function of a hetero-oligomeric complex, one could wonder why such a complex has evolved. Apart from the catalytic Stt3p, two best characterized OST subunits are Ost3p and Ost6p (Schwarz et al. 2005). Ost3p and Ost6p facilitate efficient glycosylation in a site-specific manner (Schulz & Aebi 2009). A model was proposed where different OST isoforms assist the binding of specific polypeptide substrates, via mixed disulphides and noncovalent interactions, increasing the time for the Stt3p to efficiently glycosylate sites that would otherwise be inaccessible (Schulz et al. 2009; Schulz & Aebi 2009; Jamaluddin et al. 2011; Mohd Yusuf et al. 2013; Mohorko et al. 2014). Apart from essential function in contributing to complex stability, little is known about the function of other OST subunits.

WBP1 encodes an essential type I integral membrane glycoprotein with a large luminal domain containing cleavable N-terminal signal sequence and two N-glycans, one transmembrane domain and short cytoplasmic tail with C-terminal dilysine ER retention signal (te Heesen et al. 1991; Gaynor et al. 1994). Wbp1p was the first OST subunit discovered by screening yeast cells for temperature sensitive alleles. Two temperature sensitive alleles were identified, *wbp1-1* and *wbp1-2* respectively, were both led to hypoglycosylation of several glycoproteins *in vivo* and reduced OST activity *in vitro* (S et al. 1992; S te Heesen et al. 1993). The hypoglycosylation phenotype of *wbp1-1* was found to be stronger than of *wbp1-2* (S te Heesen et al. 1993). Both mutations caused a reduction in Wbp1p levels, hence the temperature sensitive phenotype was proposed to result from the general reduction of glycosylation

(te Heesen et al. 1992). OST48, the mammalian homologue of WBP1, was found to be required for glycosylation in mammalian cells (Silberstein et al. 1992; Roboti & High 2012). Knockdown experiments with small interfering RNA (*siRNA*) resulted in reduced levels of glycosylation, similar to *wbp1* mutants (Roboti & High 2012). Currently, the only function of Wbp1p demonstrated is its essential role in OST complex formation. Deletion of *WBP1* results in decreased levels of its subcomplex partners Ost2p and Swp1p, and of Ost3/6p and Stt3p (Mueller et al. 2015). This might be the reason to the hypoglycosylation phenotype. The work of Li and colleagues showed that the luminal part of the Wbp1p transmembrane domain mediates association with the other subunits (Li et al. 2003).

In this study, we report the identification and characterization of Wbp1p conserved residues and their effect on N-linked glycosylation and the stability of OST complex. We report novel mutants that destabilize OST complex and alter glycosylation by inducing rapid degradation of other OST subunits.

Results

Site-directed mutagenesis of Wbp1p conserved residues

WBP1 is encoded by genomes of all eukaryotes that contain multi-subunit OST complexes, including vertebrates, fungi, nematodes, arthropods, plants and many protists. Wbp1 protein sequences show little variation in the length between different organisms. Polypeptide sequence alignment between 23 Wbp1p homologues was performed, including the homologues from four-subunit OST complex containing *Trichomonas vaginalis*, *Entamoeba histolytica*, *Plasmodium falciparum* and six-subunit OST complex containing *Cryptosporidium parvum* (Supplementary Figure 1). We have identified eight amino acid residues (F102, Q222, R228, N246, W256, Q313, P347 and R376, respectively) that were conserved across all sequences (Figure 1, in red) and five amino acid residues (F355, Y359, F409, S234 and D348, respectively) that were conserved in at least 20 sequences (Figure 1, in black).

Figure 1. Conserved residues of *Saccharomyces cerevisiae* Wbp1 protein.

Data from Supplementary Figure 1. N-terminal signal sequence is underlined. Transmembrane domain is highlighted in grey. Strictly conserved residues are in red while other conserved residues are in bold black.

We have developed a strategy for generating point mutations in the chromosomal copy of *WBP1* (Figure 2). In order to complement the deleterious loss of an essential Wbp1p, *LmSTT3D* was introduced on a high-copy number plasmid prior to the knockout of the *WBP1* gene with *Kluyveromyces lactis* *LEU2* cassette. Simultaneously, a plasmid was constructed carrying the wild type copy of the *WBP1* in frame with the *KanMX* marker cassette using recombination-assisted PCR targeting technique. Site-directed mutagenesis was used to generate point mutations on a plasmid copy of *WBP1* where the conserved residues were replaced by an alanine residue. Mutated version of

wbp1 together with *KanMX* cassette were amplified and reintegrated into the original *WBP1* locus using homologous recombination.

Figure 2. Strategy for the construction of *wbp1* point mutants.

(A) Yeast 'starter strain' was generated in two steps. First, yeast cells were transformed and selected for the *URA3* marker on a plasmid carrying *LmSTT3D* followed by the deletion of endogenous copy of *WBP1* using *K. Lactis* *LEU2* cassette in the . (B) Simultaneously, *WBP1* wild type copy together with sequences 50bp upstream and 200 bp downstream from the ORF were amplified from yeast genomic DNA. *KanMX* cassette was amplified from pFA6a-*KanMX4* plasmid using primers carrying sequences homologous to *WBP1* downstream region and to the plasmid region. (C) Separate PCR products were homologously recombined using yeast cells to construct *WBP1*-plasmid. (D) Phusion site-directed mutagenesis was used to generate *wbp1* point mutations on *WBP1*-plasmid. (E) Mutated version of *wbp1*-*KanMX* cassette was amplified and transformed into yeast 'starter strain'.

All of the conserved Wbp1p residues (Figure 1), three cysteine residues suggested to be involved in binding of Dol-PP-GlcNAc₂ (C111, C206 and C400, respectively) and two asparagines that are part of Wbp1 N-linked glycosylation sites (N60 and N322, respectively) were mutated to alanine residues as described above (Pathak et al. 1995).

Evaluation of the experimental system with known *wbp1* mutations

Previously isolated conditional *wbp1-1* and *wbp1-2* alleles were shown to cause temperature-sensitive growth defect and hypoglycosylation of several glycoproteins *in vivo* (te Heesen et al. 1992). We introduced *wbp1-1* (R228Y), and *wbp1-2* (F249S and S294L) mutations in the genomic copy of *WBP1* locus. In the presence of complementing *LmSTT3D* protein we analysed the effect of the two previously described *wbp1* mutants on the OST complex assembly and in its absence, we assayed for growth and glycosylation efficiency using SDS-PAGE and immunoblot analysis. The cells were first subjected to the growth on 5-FOA containing medium where the cells lacking *URA3 LmSTT3D* expression plasmid were selected and their survival was dependent on the ability of the OST to preserve all or some of its activity (Figure 3A). Both *wbp1* mutants reduced the enzyme activity at both permissive (23°) and non-permissive temperature (37°C), resulting in the temperature-sensitive growth phenotype, where *wbp1-1* showed stronger phenotype as in accordance with previously published results (te Heesen et al. 1992). As *wbp1-2* allele contains two point mutations (F249S and S297L, respectively) we introduced these mutations individually and assayed for growth on medium containing 5-FOA (Figure 3A). Individual mutations in the *WBP1* locus had no effect on enzyme activity and cell growth indicating that the temperature-sensitive phenotype of the *wbp1-2* allele is a result of cumulative effect of both mutations.

We examined the effect of *wbp1-1* and *wbp1-2* alleles on the OST activity *in vivo* in the absence of *LmSTT3D* expressing plasmid by analysing the glycosylation efficiency of yeast proteins by SDS-PAGE immunoblot (Figure 3B). Our result demonstrated that both mutants caused hypoglycosylation of all four glycoproteins analysed (i.e. CPY, Pdi1, Ost1 and Wbp1), indicating a systematic hypoglycosylation phenotype where *wbp1-1* mutants showed a more severe effect on the glycosylation efficiency. Furthermore, both mutants resulted in decreased amounts of Wbp1p, as well as Ost3p and Ost6p compared to the cells carrying either endogenous or reintegrated wild type *WBP1* copy (Figure 3B). These results were in agreement with previously published studies (te Heesen et al. 1992).

We next analysed the effect of *wbp1-1* and *wbp1-2* alleles on OST complex stability (Figure 3C). Our results showed reduced steady state levels of Wbp1p, Ost3p and Ost6p in both mutants implying that the OST complex is destabilized (Figure 3B). We used the previously developed SILAC pulse-chase method to analyse protein degradation rates of OST subunit proteins (Mueller et al. 2015). Under the assumption that the OST complex is stable with all subunits present in similar amounts at stoichiometric level in the wild type yeast cells, a perturbation could lead to destabilization of some or all subunits resulting in a faster degradation, with lower amounts of destabilized subunits in the complex. As such, we can analyse the complex stability by calculating the degradation rates of OST

subunits during exponential growth. Yeast microsomal fractions were prepared from $\Delta wbp1$, $wbp1-1$ and $wbp1-2$ cells, proteins were extracted, processed for mass spectrometry and quantified using SRM MS. As previous result had indicated, both mutants resulted in higher turnover of Wbp1p. Degradation of several other proteins, including Ost3p, Ost6p, Ost2p, Swp1p, and to a lesser extent, Ost5p and Stt3p was observed as well (Figure 1C; Supplementary Table 1). This phenotype was similar to the phenotype observed for the $wbp1$ deletion strain further indicating that these mutations destabilize Wbp1p resulting in its degradation. The lack of Wbp1p in turn destabilized the rest of the OST complex, thus most of the remaining subunits are affected as well. Our findings are in agreement with previously published results where the lack of Wbp1p was already shown to cause increased degradation rates of the subcomplex partner proteins Ost2 and Swp1, as well as Ost3, Ost6, Ost5 and Stt3 proteins (Mueller et al. 2015).

Figure 3. *wbp1-1* and *wbp1-2* alleles result in OST complex destabilization.

(A) 5-FOA spotting assay for the analysis of *wbp1* growth phenotypes. Yeast wild type cells and cells where the endogenous copy of *WBP1* locus was replaced with either the *K.lactis* *LEU2* cassette, wild type *WBP1* or different *wbp1* alleles were complemented by *URA3 LmSTT3D* expression plasmid. Serial dilutions of wild type and mutant cells were spotted on medium containing 5-FOA and incubated at 23°C or 37°C for five days. Mutations that inactivate the OST enzyme do not support the growth of the cells. (B) Immunoblot analysis of *wbp1* strains. SDS extracts were prepared from wild type cells or mutant cells where the endogenous *WBP1* locus was replaced by either the *K. lactis* *LEU2* cassette, the wild type *WBP1* or *wbp1-1* and *wbp1-2* loci. Some of the cells were carrying

LmSTT3D expression plasmid as indicated. Equal amounts of protein were separated on a 10% SDS-PAGE gel and transferred to nitrocellulose membrane, followed by detection with specific antibodies. Hexokinase (HXK) was used as a loading control. (C) k_{DEG} values of OST subunits in *wbp1-1*, *wbp1-2* or in cells deleted in *WBP1*, all carrying *LmSTT3D* expression plasmid. After labelling of yeast proteins with heavy arginine and lysine, cells were transferred to light medium and sampled at different time points. Proteins were prepared for mass spectrometry and light-to-heavy (L/H) ratios for peptides detected by SRM. Degradation rates were calculated as described. Error bars represent SD of three biological replicates. * $p < 0.001$, ** $p < 0.01$, *** $p < 0.05$. The dashed line indicates a half-life less than 12 hours representing eight cell divisions.

Novel *wbp1* mutations affect OST activity

Polypeptide sequence alignment of Wbp1p homologues revealed residues conserved between 23 species known to contain multi-subunit OST complexes (Figure 1, Supplementary Figure 1). These Wbp1p residues, including two N-linked glycosylation sites and three cysteine residues, were mutated to alanine in the presence of complementing *LmSTT3D* and their effect on cell growth in the presence of 5-FOA was examined (Supplementary Figure 2). Out of 18 mutations analysed, single amino acid changes in three residues (F102A, W256A and Y284A, respectively) resulted in reduced enzyme activity and temperature sensitivity at 37°C while the other mutations had no effect on cell growth on 5-FOA containing medium (Figure 4A; Supplementary Figure 2). Of the three mutants, the replacement of tryptophan at position 256 with an alanine residue had the most severe effect causing the complete loss of OST activity at non-permissive temperature (37°C). The other two mutations were capable of supporting cell growth at non-permissive temperature although they grew slower as compared to the cells with reintegrated wild type *WBP1* copy (Figure 4A).

We then examined the effect of the novel *wbp1* alleles on the OST activity *in vivo* in the absence of *LmSTT3D* expressing plasmid by analysing the glycosylation efficiency of yeast glycoproteins by SDS-PAGE immunoblot (Figure 4B). In line with growth analysis results, W256A mutation resulted in the most severe hypoglycosylation of all four glycoproteins analysed (i.e. Wbp1p, Ost1p, CPYp and Pdi1p) as compared to the other two mutations, indicating a systemic hypoglycosylation phenotype. The other two mutants, *F102A* and *Y284A* respectively, showed less severe hypoglycosylation phenotype as compared to *W256A* mutant, where *F102A* mutation resulted in a more reduced OST activity as compared to *Y284A* mutation (Figure 4B).

To investigate OST complex stability, we conducted a pulse chase SILAC SRM experiment and determined degradation rates for all OST subunit proteins as described above (Figure 4C). The two mutations resulting in stronger growth and hypoglycosylation phenotypes, *W256A* and *F102A* respectively, induced degradation of Wbp1p where the degree of Wbp1p degradation correlated with

the severity of the two phenotypes. Both mutations resulted in degradation phenotype similar to *wbp1-1* and *wbp1-2* alleles, with two exceptions. Similar to previously described *wbp1* strains, OST subunits Ost2p, Swp1p, Ost3p and Ost6p were severely degraded in *W256A* strain, however Ost5p and Stt3p were more stable in this mutant. *Wbp1p* F102A mutation resulted in degradation of all of the OST subunits degraded in *wbp1-1* and *wbp1-2* except for Ost2p, which was stable in this mutant. Lastly, all OST subunits were stable in *Y284A* (Figure 4C; Supplementary Table 1).

Figure 4. *Wbp1p* mutations F102A, W256A and F102A reduce OST activity through complex destabilization.

(A) 5-FOA spotting assay for the analysis of *wbp1* growth phenotypes. Yeast cells where the endogenous copy of *WBP1* locus was replaced with either the *K.lactis* *LEU2* cassette, wild type *WBP1* or different *wbp1* alleles were complemented by *URA3 LmSTT3D* expression plasmid. Serial dilutions of wild type and mutant cells were spotted on medium containing 5-FOA and incubated at 23°C or 37°C for five days. Mutations that inactivate the OST enzyme do not support the growth of the cells. (B) Immunoblot analysis of *wbp1* strains. SDS extracts were prepared from mutant cells where the endogenous *WBP1* locus was replaced by the wild type *WBP1* or the mutated *wbp1* loci. Equal amounts of protein were separated on a 10% SDS-PAGE gel and transferred to nitrocellulose membrane, followed by detection with specific antibodies. Hexokinase (HXK) was used as a loading control. (C) k_{DEG} values of OST subunits in different *wbp1* strains carrying *LmSTT3D* expression plasmid. After

labelling of yeast proteins with heavy arginine and lysine, cells were transferred to light medium and sampled at different time points. Proteins were prepared for mass spectrometry and light-to-heavy (L/H) ratios for peptides detected by SRM. Degradation rates were calculated as described. Error bars represent SD of three biological replicates. * $p < 0.001$, ** $p < 0.01$, *** $p < 0.05$. The dashed line indicates a half-life less than 12 hours representing eight cell divisions. (D) Steady state levels of OST subunit proteins in different *wbp1* strains carrying *LmSTT3D* expression plasmid. Yeast wild type cells were grown in heavy arginine and lysine medium, while *wbp1* mutant cells were grown in medium containing light amino acids. Equal amounts of cells were mixed, proteins extracted, and peptides were processed for mass spectrometry. L/H ratios for peptides were detected by SRM. Subunit abundance relative to wild type was calculated as described. Error bars represent the 95% confidence interval of the average of two biological replicates.

As pulse-chase experiments have been shown to lack sensitivity when it comes to detecting small stability differences between different proteins, we examined the effect of *wbp1* alleles on OST complex stability by monitoring steady state levels of OST subunits (Mueller et al. 2015). We performed SILAC experiment where wild type cells grown in medium containing heavy arginine and lysine amino acids were mixed 1:1 with mutant cells grown in medium containing light amino acids. Membranes were isolated, proteins digested and peptides were prepared for SRM MS measurement (Figure 4D). In the control measurement where yeast wild type cells and cells with reintegrated wild type *WBP1* were pooled together, all OST subunit proteins had a normal level (100%) (Figure 4D). Distinct results were observed for different *wbp1* strains. Wbp1p W256A mutation reduced the levels of Wbp1p (to 24%), Ost2p (to 37%), Swp1p (to 65%), Ost3p (to 49%) and Ost6p (to 40%) while the levels of Ost1p, Ost5p and Stt3p were not affected. Together with pulse-chase analysis, these results indicate that W256A mutation severely destabilized Wbp1p resulting in destabilization of OST complex. These results are in accordance with previously published work showing that *WBP1* deletion drastically alters the amounts of Ost2p, Swp1p, Ost3p and Ost6p (Mueller et al. 2015). Similar to pulse-chase evaluation, steady state levels of Wbp1, Swp1, Ost3, and Ost6 proteins in *F102A* mutant were decreased (45%, 50%, 60% and 53%, respectively) while the level of Ost2p was not affected. This result indicates that phenylalanine at position 102 is important for Wbp1p stability as well as for the Wbp1p interaction with Swp1p. Contrary to protein degradation analysis, Y284A mutant resulted in the decreased Swp1p (to 50%) and Ost2p (to 70%) levels indicating that this residue is not crucial for Wbp1p stability but for interaction with Swp1 and Ost2 proteins.

The effect of individual point mutations on cell growth and OST activity was examined in the other Wbp1p residues. As mentioned above, these additional mutations had no effect on cell growth on 5-FOA containing medium (Supplementary Figure 2). Using 5-FOA counter-selection *wbp1* mutant cells without *LmSTT3D* expression plasmid were selected and their growth on YPD medium was examined.

Similar to 5-FOA containing medium, no growth phenotypes were detected (data not shown). When we then examined the effect of these *wbp1* strains on the OST activity *in vivo* in the absence of *LmSTT3D* expressing plasmid by analysing the glycosylation efficiency of yeast glycoproteins by SDS-PAGE immunoblot, no evident hypoglycosylation phenotypes were detected either (Supplementary Figure 3).

Mutations affecting the addition of sugar residues in the luminal assembly of the LLO do not show any detectable growth defect, but combined accumulation of suboptimal lipid-linked oligosaccharides and reduced oligosaccharyltransferase activity (such as in *stt3-3* mutant) results in synthetic phenotype with growth defects at non-permissive temperature of 37°C (Aebi et al. 1996). It has been demonstrated previously that single mutations of *ALG5*, *ALG6* or *ALG8*, involved in glucosylation of the LLO, in *wbp1-1* cause severe growth defect even at permissive temperature of 30°C (Stagljar et al. 1994). We replaced *ALG3* gene with *NatNT2* cassette in *wbp1* strains. The inactivation of the nonessential *ALG3* gene results in the accumulation of lipid-linked GlcNAc₂Man₅. No observable growth arrest resulted in majority of the additional *wbp1* double mutants with two exceptions (Supplementary Figure 4). Double mutants *F355AΔalg3* and *F409A Δalg3* resulted in mild temperature sensitivity at 37°C (Supplementary Figure 4). When we examined the effect of the double mutants on protein glycosylation by SDS-PAGE immunoblot, no synthetic phenotypes were observed (data not shown).

In order to examine if Wbp1p affects glycosylation of specific substrate proteins, SILAC coupled to parallel reaction monitoring (PRM) MS-based technique was used to analyse glycosylation occupancy on yeast microsomal glycoproteins (Poljak et al.; in preparation). Due to time limitations, we only performed a preliminary experiment using one biological replicate for some of the *wbp1* strains. Wild type cells grown in medium containing heavy arginine and lysine amino acids were mixed 1:1 with mutant cells grown in medium containing light amino acids. Membranes were isolated, proteins digested and N-linked glycans were cleaved by EndoH to maintain the first GlcNAc residue of the glycan on the protein. The resulting peptides were analysed by LC-MS/MS and site occupancies relative to the reference strain were calculated for *wbp1* strains (Supplementary Table 2). From the preliminary results of the PRM MS analysis ten out of twelve *WBP1* mutations caused hypoglycosylation of Ero1p (Q222A, S234A, Q313A, P347A, D348A, F355A, Y359A, R376A, F409A and N322A, respectively), where the extent of hypoglycosylation varied in different mutants. Other glycoproteins were affected as well, including Wbp1, CPY, Erg3, Crh2, and Mnn5 proteins. However, the preliminary results need to be confirmed using additional biological replicates. Moreover, although SDS-PAGE immunoblot analysis did not reveal evident decrease of the OST complex subunits, a SILAC SRM experiment needs to be done in order to investigate OST complex stability in those mutants (Supplementary Figure 3).

Discussion

The yeast OST complex is composed of eight subunits where the expression of a majority of the subunits is essential for the cell viability. Except for the catalytic function of Stt3p and the function of isoform-defining Ost3/6p, only little is known about the role of the other subunits. Although several temperature sensitive mutants of Wbp1p were isolated previously, these mutants did not provide information about the role of Wbp1p beyond its importance for the OST complex integrity. Residues conserved between 23 distinct species ranging from single cell eukaryotic organisms to mammals were identified and mutated into alanine using a high throughput strategy for generating point mutations in the chromosomal copy of *WBP1*. In order to further characterize previously isolated conditional *wbp1-1* and *wbp1-2* alleles, we introduced *wbp1-1* (R228Y), and *wbp1-2* (F249S and S294L) mutations in the genomic copy of *WBP1* locus. In accordance with former results, both *wbp1* mutants reduced the enzyme activity at both permissive (23°) and non-permissive temperature (37°C), while the individual *wbp1-2* mutants (F249S and S297L, respectively) had no effect on the cell growth indicating that the temperature-sensitive phenotype of *wbp1-2* mutant is a result of cumulative effect of both mutations. Both, *wbp1-1* and *wbp1-2*, mutants caused systematic hypoglycosylation of glycoproteins. By examining OST subunits protein degradation rates, we have shown that the both mutants destabilize Wbp1p resulting in its degradation. The lack of Wbp1p in turn destabilized the rest of the OST complex, thus most of the remaining subunits (Ost3p, Ost6p, Ost2p, Swp1p, and to a lesser extent, Ost5p and Stt3p) are degraded as well. This phenotype was similar to the phenotype observed for the *wbp1* deletion strain and are in agreement with previously published results (Mueller et al. 2015). When we examined the effect of the alanine replacements of Wbp1p conserved residues, only three mutations (F102A, W256A and Y284A, respectively) resulted in reduced enzyme activity and temperature sensitivity at non-permissive temperature of 37°C. The replacement of tryptophan at position 256 with an alanine residue had the most severe effect, causing the complete loss of OST activity at 37°C and systematic hypoglycosylation at 30°C, similar to *wbp1-1* mutant. Although less severe, F102A mutation had a similar effect. Both, W256A and F102A, alleles destabilized Wbp1p resulting in destabilization of OST complex. Interestingly, the mutation of phenylalanine at position 102 caused degradation and reduced steady state levels of all of the OST subunits degraded in *wbp1-1* mutant except for Ost2p, which was stable in this mutant. Given the proposal of Mueller and colleagues that one can define interactions between different OST subunits by measuring their turnover rates or steady state levels in different mutants, such a result might indicate that the Ost2p is less important for the assembly of the first subcomplex and that in certain condition could be stable on its own (Mueller et al. 2015). The Y284A mutant resulted in the reduced growth at non-permissive temperature of 37°C and hypoglycosylation of some glycoproteins. Steady state protein level

measurements revealed that, although Wbp1p is stable, the amounts of Swp1p and Ost2p are decreased in this mutant. These results indicate that tyrosine residue at position 284 is important for the interaction of Wbp1p with Swp1 and Ost2 proteins. Taken together, these results demonstrate that W256A, F102A and Y284A mutations affect OST activity through complex destabilization, either as a result of Wbp1p destabilization itself or due to impaired interaction with subcomplex subunits. The other mutations, including the mutations affecting the two N-linked glycosylation sites and three cysteine residues, had no effect on the cell growth. Although these mutations did not result in hypoglycosylation of four glycoproteins examined by immunoblot, we identified several mutations that affected glycosylation of six glycoproteins examined by the preliminary MS-based glycosylation occupancy analysis of yeast microsomal fractions. Albeit these results still need to be verified, it is tempting to postulate the role of Wbp1p in influencing the glycosylation of specific substrate proteins. Previous reports have demonstrated that the knockdown of the mammalian OST1 homologue ribophorin I resulted in hypoglycosylation of some membrane proteins while soluble proteins were not affected (Wilson & High 2007; Wilson et al. 2008). Furthermore, deletion of *OST3* and *OST6* in yeast cells have been shown to affect glycosylation of specific proteins (Schulz & Aebi 2009). Another possibility to gain insight into the role of Wbp1p would be to solve the crystal structure of its luminal domain, similar to Ost6p where the crystal structure of its luminal domain helped elucidate the function of Ost3/6p subunits (Schulz et al. 2009).

Materials and Methods

Plasmids

Plasmids and primers used in this study are listed in Supplementary Table 3 and 5. Standard cloning and yeast genetic techniques were used (Knop et al. 1999; Gibson 2009). A pRS313 plasmid containing *WBP1* locus and *KanMX* cassette was constructed. *WBP1* locus (starting from 33 bp upstream until 250bp downstream of the ORF) was amplified from wild type genomic DNA using primers P1-wbp1-pRS313_Fw, flanked with pRS313 plasmid homologous region, and P2-wbp1-Rev. *KanMX* cassette was amplified from pFA6a-KanMX4 plasmid using a forward primer containing *WBP1* homologous region (P3-Kan-wbp1-Fw) and a primer containing pRS313 homologous region (P4-Kan-Wbp1-Rev). The pRS313 plasmid was digested with EcoRI restriction enzyme that yielded a linear plasmid DNA with ends homologous to the regions of *WBP1* and *KanMX* PCR products. The two PCR products and digested plasmid were co-transformed into wild type yeast cells resulting in the generation of recombined *WBP1*-plasmid. Transformed cells were grown overnight on rich medium (YPD) and replica plated onto the selective medium containing geneticin (G418) the next day. The plasmid was recovered from yeast cells as described before and amplified in *E.coli*. The plasmid was doubly digested and sequenced to ensure proper gene integration. Phusion site-directed mutagenesis was used to generate point mutations in the *WBP1* ORF on the *WBP1*-plasmid as described before. Shortly, primers were designed to anneal back-to-back to the plasmid where the desired mutation was located in the middle of the forward primer. Primers used for mutagenesis are listed in Supplementary Table 5. The primers were first phosphorylated, *WBP1*-plasmid was PCR amplified and the mutated product was circulated by ligation with T4 ligase. The product was amplified in *E.coli* and the mutations were confirmed by sequencing.

Strains

Strains used in this study are listed in Supplementary Table 4. Standard cloning and yeast genetic techniques were used (Knop et al. 1999). If not mentioned otherwise, all strains were grown at 30°C. The 'wild type' strain (KP4 strain) used in this study was generated by deleting *ARG4* gene in BY4742 (Euroscarf) yeast strain using Cre/loxP system as described before (Güldener et al. 1996). Shortly, the *KanMX* cassette flanked with two direct repeats of *loxP* sites and homologous regions of *ARG4* was amplified from pUG6 plasmid and transformed into BY4742 cells. Transformed cells were grown overnight on YPD medium and replica plated onto the selective medium containing G418 the next day. The proper integration of the cassette and knock out of *ARG4* was confirmed by PCR. The resulting yeast strain was transformed with pSH47 plasmid that carries Cre recombinase under the control of galactose (*GAL1*) promoter. Shifting cells to galactose medium resulted in the excision of *KanMX*

cassette with a remnant *loxP* site. The complete loss of the cassette was confirmed by PCR. This strain was grown on 5-Fluoroorotic acid (5-FOA) allowing for the selection of the cells that have lost the pSH47 plasmid. The resulting strain, KP4 strain, was termed wild type in this study. In the next step, KP4 strain was transformed with pLmSTT3 plasmid and plasmid-containing cells were selected on -URA plates. Yeast *WBP1* gene was replaced by *K. lactis LEU2* cassette amplified from pUG73 plasmid (using Kl-leu2-Wbp1-Fw and Kl-Leu2-Wbp1-Rev primers) resulting in the deletion of *WBP1* ORF and sequences 133bp upstream and 163bp downstream from the ORF. After transformations, the cells were selected on -URA-LEU plates. The knockout of *WBP1* gene was checked by PCR (using Wbp1-Fw-Check and Wbp1-Rev-Check primers). Resulting strain was termed KP5, or 'starter strain'. Mutant *wbp1* genes and *KanMX* cassette were amplified from mutated *WBP1*-plasmid (using PC-Wbp1-Fw and PC-WBP1-Rev primers) and transformed into KP5 strain. Transformed cells were grown overnight on YPD medium and replica plated onto the selective medium containing G418 the next day. The proper reintegration of mutated *wbp1* locus was confirmed by PCR and sequencing. In most cases, mutant cells were grown on the medium containing 5-FOA allowing for the selection of the cells that have lost the pLmSTT3D plasmid.

Spotting assay for growth

To determine the growth rate of yeast transformants carrying *wbp1* mutants, 15 ODs of cells were collected after the strains were grown to early log phase in either -URA or YPD media at 30 °C. Two microliters of 1:10 serial dilutions of the cells was spotted on either 5-FOA or YPD plates, respectively, and incubated at 25, 30, or 37 °C for 5 or 2 days, respectively.

Immunoblot analysis

Cultures were grown in YPD medium to exponential phase. Cells were lysed with glass beads in sample buffer by vortexing at 4°C for 15 min. The sample buffer contained 2% SDS, 62.5 mM Tris/HCl, pH 6.8, 10% glycerol, 6 M urea, 5% β-mercaptoethanol, 0.02% bromophenol blue, protease inhibitor (Complete, Roche), 5 mM phenylmethylsulfonyl fluoride and 25 mM EDTA. Proteins were dissolved at 37°C for 20 min. Equal amounts of protein were loaded on 10% polyacrylamide gels. Proteins were blotted onto a nitrocellulose membrane. The membrane was hybridized with a primary antibody, washed, and hybridized with appropriate secondary antibodies. Antibodies used are listed in Supplementary Table 5. Proteins were detected with ECL solution (GE Healthcare, Amersham) and light sensitive films (Super RX, Fuji Medical X-Ray Film).

SILAC chase

Yeast cells were grown to exponential phase in SD-URA medium supplemented with 20 mg/L heavy [$^{13}\text{C}_6/^{15}\text{N}_2$] L-lysine and [$^{13}\text{C}_6$] L-arginine (Cambridge Isotope laboratories). Cells were collected by filtration, washed with SD medium without arginine and lysine, and resuspended in SD medium containing light isotopes of arginine and lysine to obtain $\text{OD}_{600} = 0.5$. At different time points, 50 OD of cells were collected, frozen in liquid nitrogen, and stored at -80°C followed by the preparation for mass spectrometry.

Steady-state SILAC

Wild type cells were grown in synthetic complete medium containing 20 mg/L heavy [$^{13}\text{C}_6/^{15}\text{N}_2$] L-lysine and [$^{13}\text{C}_6$] L-arginine (Cambridge Isotope laboratories). Mutant cells were grown in synthetic complete medium containing 20 mg/L light [$^{12}\text{C}_6/^{14}\text{N}_2$] L-lysine and [$^{12}\text{C}_6$] L-arginine. Cells were harvested in early log phase ($\text{OD}_{600\text{nm}} = 0.8\text{-}1.2$) by centrifugation and mixed 1:1 (w/w) before being processed for mass spectrometry.

Sample preparation for mass spectrometry

Yeast microsomal fractions were prepared as described previously (Mueller et al. 2015). Shortly, cells were lysed and microsomal fractions were collected by high spin centrifugation at 16,000xg, 4°C for 20 min. Proteins were processed using the filter-assisted sample preparation (FASP) protocol (Wiśniewski et al. 2009). After reduction and alkylation, proteins were digested with Lys-C (20 $\mu\text{g}/\text{mL}$; Wako Pure Chemical, Richmond, VA) and trypsin (20 $\mu\text{g}/\text{mL}$; Promega) endopeptidases. When mentioned, protein digestion was directly followed by EndoH (500 U; New England BioLabs) endoglycosidase treatment. Peptides were desalted using C18 ZipTips (Millipore) and dried using speed vacuum. Desalted peptides were resuspended in ACN/ H_2O (3:97 (v/v)) with formic acid (FA; 0.1% (v/v)) and analysed by LC-ESI-MS/MS. Retention time iRT peptides (Biognosys) were added to all samples in ratio of 1:40.

SRM mass spectrometry

For each sample, 4 μl was injected onto a nano-frit column (15 cm \times 75 μm ; OD 375 μm ; beads, Magic C18 AQ, 3 μm , 200 \AA ; Bischoff Chromatography) kept at 50°C and connected to a spray tip (PicoTip emitter, FS360-20-10-N-20-C12; New Objective; MS Wil) coupled to an Eksigent nanoLC-Ultra 1D plus (AB Sciex). Peptides were eluted using a gradient from 3 to 35% solvent B (99% (v/v) acetonitrile, 0.1% (v/v) formic acid) for 57.5 min at a flow rate of 500 nL/min. Targeted SRM analysis was performed on

a QTRAP 5500 (AB Sciex) supplied with a nanospray ion source. Interface temperature was 170°C, ion spray voltage 2000–2500 V, ion source gas pressure 6–10 psi, curtain gas pressure 25 psi, and collision gas was set to high. Declustering potential had a value of 100, collision cell exit potential of 13, and entrance potential of 10. Retention time windows for the transitions were 5-min and a target scan time was 3 s. The scheduled transition list contained 377 transitions (Appendix Table 5). Results from the SRM runs were exported to Skyline software, and peaks were integrated (MacLean et al., 2010). The peaks were manually inspected and adjusted to ensure proper peak picking and peak integration.

PRM mass spectrometry

Peptides were separated on HSS T3 column (78 μm \times 150 mm, 1.8 μm) packed with C18 material (Waters) on ACQUITY UPLC system (Waters). Peptides were eluted using the gradient of 2 - 35% solvent B (99% (v/v) ACN, 0.1% (v/v) FA) over 90 min at a flow rate of 0.3 $\mu\text{l}/\text{min}$. MS analysis was performed on Q Exactive HF instrument (Thermo Scientific). Samples were analysed using two PRM methods at an Orbitrap resolution of 30 000 or 60 000, based on scheduled inclusion lists containing the 175 and 128 target precursor ions, respectively, including retention time iRT standard peptides (Biognosys) (Appendix Table 1). The full scan event was collected using a m/z 50–1400 mass selection, an Orbitrap resolution of 60 000 (at m/z 400), target automatic gain control (AGC) value of 3×10^6 and a maximum injection time of 30 ms. The PRM scan events used an Orbitrap resolution of 30 000 or 60 000, maximum fill time of 30 or 110 ms respectively, an AGC value of 1×10^6 and with an isolation width of 2 m/z . Fragmentation was performed with a normalized collision energy of 28 and MS/MS scans were acquired with a starting mass of m/z 150. Scan windows were set to 10 min. Results from the SRM runs were exported to Skyline software, and peaks were integrated (MacLean et al., 2010).

Calculation of protein degradation rates

The degradation rate calculation was done by normalizing the rate of loss of old proteins to the dilution of protein content by cell division. The loss rate of old protein from the cell (k_{LOSS}) was calculated from the time course of isotopic ratios (Larrabee et al. 1980). Values were normalized to the dilution of protein content by cell division. This was done by subtraction of k_{DIL} (= k_{LOSS} of the stable reference protein Rpl5p). Protein half-lives were calculated as $t_{1/2} = \ln(2)/k_{\text{DEG}}$. Proteins with $t_{1/2}$ greater than 12 hours, corresponding to 8 cell divisions, were considered stable, otherwise they were considered instable.

Calculation of abundance of OST proteins

Light to heavy intensity ratio (L/H) ratios were calculated for each peptide. The amount of OST subunits relative to wild type was calculated from the average L/H over all peptides of a protein. Values were normalized by dividing by the ribosomal control proteins Rpl5p and Rps1a of each replicate. Results of three biological replicates were expressed as percentage protein level compared to wild type.

Calculation of glycosylation site occupancy

The L/H ratio for glyco-peptides modified with HexNAc was used to calculate the relative site occupancy for the given peptide/ glycosylation site. The relative site occupancy was normalized for expression differences between heavy labelled reference wild type strain (H) and the mutant strains (L) by dividing the L/H intensity ratio for the occupied glyco-peptide by the median of L/H intensity ratios reported for all non-glyco (i.e. not containing a N-X-T/S sequon) peptides from the same protein as the glyco peptide.

Chapter 4b

Supplementary Information to Chapter 4

Supplement Figure 1. Polypeptide sequence alignment of Wbp1p homologues from 23 organisms.

Strictly conserved residues are highlighted in red; other conserved residues are in red boxes.

Supplementary Figure 2. 5-FOA spotting assay for the analysis of *wbp1* mutant growth phenotypes.

Yeast cells where the endogenous copy of *WBP1* locus was replaced with either the wild type, mutated *wbp1*, or *K. lactis* *LEU2* cassette were complemented by *URA3 LmSTT3D* expression plasmid. Serial dilutions of wild type and mutant cells were spotted on medium containing 5-FOA and incubated at 23°C or 37°C for five days. Mutations that inactivate the OST enzyme do not support the growth of the cells.

Supplementary Figure 3. Immunoblot analysis of *wbp1* mutants.

SDS extracts were prepared from mutant cells where the endogenous *WBP1* locus was replaced by either the wild type *WBP1* or different *wbp1* mutant loci. Equal amounts of protein were separated on a 10% SDS-PAGE gel and transferred to nitrocellulose membrane, followed by detection with specific antibodies. Hexokinase (HXK) was used as a loading control.

Supplementary Figure 4. YPD spotting assay for the analysis of *wbp1* mutant growth phenotypes.

Yeast wild type cells and cells where the endogenous copy of *WBP1* locus was replaced with different *wbp1* mutants carrying *URA3 LmSTT3D* expression plasmid were grown on medium containing 5-FOA and incubated at 23°C for five days. Mutant cells that do not contain *LmSTT3D* plasmid were selected and *ALG3* loci was deleted using *NatNT2* cassette. Serial dilutions of the *wbp1* mutant cells with and without *ALG3* locus were spotted on YPD medium and incubated at 23°C, 30°C or 37°C for one to two days.

Supplementary Table 1. Protein half-lives of OST subunit proteins in different *wbp1* mutant strains.

	<i>wbp1-1</i>	<i>wbp1-2</i>	Δ <i>wbp1</i>	W256A	Y284A	F102A
Wbp1p	1.3 h	0.9 h	/	1.5 h	10.2 h	2.8 h
Ost2p	0.8 h	0.8 h	1.3 h	1.3 h	50 h	30 h
Swp1p	0.9 h	0.5 h	1 h	1.5 h	9.4 h	1.9 h
Ost1p	9 h	10.9 h	28.9 h	31.2 h	45.2 h	28.9 h
Ost5p	3.2 h	2.4 h	7.2 h	10.8 h	9.4 h	4.2 h
Stt3p	4.3 h	3.4 h	4.3 h	10.8 h	9.9 h	5 h
Ost3p	1.5 h	1.2 h	2.2 h	1.1 h	13.3 h	2.9 h
Ost6p	1.6 h	1.2 h	2.8 h	1.1 h	8.1 h	1.9 h

Supplementary Table 2. Relative glycosylation occupancy in different *wbp1* strains.

Chapter 5

Concluding Remarks & Future Perspectives

Concluding remarks and future perspectives

N-linked glycosylation is an essential, omnipresent modification of proteins that adds an additional level of biological information to polypeptides, not present on the genomic level (Cummings 2009). The glycans attached to proteins have distinct roles; they contribute in protein folding, quality control, stability and solubility, they mediate interaction between cells, and can be involved in modulating immune responses (Helenius 2001; Helenius & Aebi 2004). Although glycans are the most versatile and elaborate protein modification, occurring through the extensive and diverse remodelling by numerous enzymes in the Golgi, the preceding transfer of the glycan onto a protein in the ER is highly consistent and conserved among all three domains of life (Samuelson et al. 2005). The remarkable extent of conservation among eukaryotic organisms allows investigating basic principles of N-linked protein glycosylation in the model organism *Saccharomyces cerevisiae*. The basic mechanism of glycan transfer involves the assembly of the glycan on isoprenoid lipid carrier followed by the *en bloc* transfer of the glycan to an asparagine side chain within signature N-X-S/T sequon on the substrate protein (Breitling & Aebi 2013). Due to the conservancy between yeast and human pathways, discoveries from yeast were used to characterize the cause of congenital disorders of glycosylation (CDGs) associated with the pathway defects in humans (Freeze 2006; Haeuptle & Hennet 2009). On the other hand, high homology of the central enzyme involved in the glycan transfer, the oligosaccharyltransferase (OST), helps in elucidating its function. Fungal, mammalian and plant OSTs are multi-subunit complexes located at the ER membrane, where both attributes restrict their enzymatic and structural characterization. Nonetheless, Stt3p was identified as a catalytic subunit and based on the crystal structure of its bacterial homologue PglB, the mechanism of the glycosylation reaction has been proposed (Lizak et al. 2013). Apart from the assistance in site-specific glycosylation by the non-essential, isoform defining Ost3 and Ost6 subunits, the roles of the remaining complex subunits are still only poorly understood.

The main objective of this thesis was the *in vivo* study of the activity of OSTs from yeast *Saccharomyces cerevisiae* and *Trypanosoma brucei*. The *in vivo* study of the OST activity has largely relied on the immunoblot analysis of a small number of known OST substrates, such as carboxypeptidase CPY. Although a valid approach for the analysis of a systemic impact of the alternations in the N-linked glycosylation of proteins, this method is highly disadvantageous when one wants to examine glycoproteins for which there is no appropriate antiserum available and/or wants to gain qualitative statements about glycosylation at individual sites. Furthermore, as recent studies have demonstrated that Ost3/6p subunits have specifically affected glycosylation on subset of protein substrates, new methods that can follow glycosylation of a wide range of substrates had to be developed (Schulz & Aebi 2009). For this purpose mass spectrometry proved to be a useful tool for measuring N-linked

glycosylation site occupancy in yeast (Schulz et al. 2009; Xu et al. 2015; Yeo et al. 2016; Zacchi & BL Schulz 2016).

One of the crucial accomplishments described in this thesis is a novel method for the identification and relative quantification of glycosylation site occupancy and the abundance of glycoproteins, described in the second chapter. We have used parallel reaction monitoring (PRM), a novel mass spectrometric technique, in combination with stable isotope labelling (SILAC) to study OST activity *in vivo* on a wide range of polypeptide substrates. As opposed to previous studies, we analysed membrane and luminal proteins that eliminated the analytical bias present in the complementary approaches that allowed us to monitor all of the OST glycoproteins (Wbp1p, Ost1p and Stt3p) as well as model glycoproteins, CPY and Pdi1. We have successfully used this technique to investigate protein substrate specificities of Ost3 and Ost6 subunits, as well as site-specific polypeptide preference of different OSTs from *S. cerevisiae* and *T. brucei*. As the study of multi-subunit OST complexes is challenging due to their complicated organisation and presence of different isoforms, the discovery of single-subunit OSTs homologous to *STT3* in protozoan organisms that can functionally replace the yeast OST complex, allowed for an easier investigation of basic mechanisms of eukaryotic N-linked glycosylation (Castro et al. 2006; Nasab, Benjamin L Schulz, et al. 2008; Hese et al. 2009; Izquierdo et al. 2009). Yeast as a model organism where yeast genetics can be easily applied to modify endogenous N-linked glycosylation pathway and distinct OSTs expressed, offers an excellent system to address basic questions regarding the pathway in eukaryotes.

Using SILAC strategy combined with PRM, we examined the influence of the suboptimal LLO donor substrate on the glycosylation efficiency of the yeast endogenous OST, described in the second chapter. Previous kinetic studies of single and multi-subunit OSTs have revealed that LLO structure-mediated effect on polypeptide substrate binding affinity is a conserved property of the eukaryotic OSTs that can be assigned to the *STT3* active site (Kelleher et al. 2007). We have demonstrated that the polypeptide binding affinity of OST is influenced by the suboptimal LLO donor substrate. These results were in agreement with previous results showing that LLO binding induces conformational changes in the active site where the more complex LLOs promote stronger interaction of the polypeptide substrate with the enzyme (Breuer & Bause 1995; Gibbs & Coward 1999; Karaoglu et al. 2001).

Combining yeast genetics with different analytical methods in the third chapter allowed for detailed analysis of LLO specificity of different single subunit OSTs from *T. brucei* paralogues (*TbSTT3A*, *TbSTT3B* and *TbSTT3C*, respectively). In short, *TbSTT3B* and *TbSTT3C* preferred more complex LLO substrates, while *TbSTT3A* preferred LLOs lacking c-branch mannose residues. Furthermore, structure to function analysis identified regions responsible for the preference of *TbSTT3s* towards specific LLO substrates. This approach was further used in combination with SILAC PRM method to identify polypeptide

preferences of distinct *TbSTT3* paralogues showing that *TbSTT3A* and *TbSTT3C* have similar preference for acidic polypeptides, as in agreement with previous observations (Izquierdo et al. 2009). A specific region, termed region 1, was identified which influenced the preference of *TbSTT3s* towards the polypeptide substrates. Sequence comparison indicated that this region is homologous to the external loop 5 (EL5), known to interact with the polypeptide substrate in bacterial *STT3* homologue *PglB* (Lizak et al. 2011). Therefore, we speculate that region 1, identified in the eukaryotic *STT3s* could be a functional equivalent to the EL5 described in *PglB*. Furthermore, considering the results brought in chapter two and three, it is interesting to postulate that it is the conformational change of region 1 that occurs upon binding of the LLO to the active site of the eukaryotic *STT3*, and in that way affects the polypeptide preference of eukaryotic OSTs, as EL5 has been proposed to be involved in the glycosylation mechanism of bacteria in the similar way (Lizak et al. 2011). More experimental work and crystal structures of eukaryotic OSTs will provide insights into the molecular basis of polypeptide specificity.

Enzyme kinetic experiments have revealed that higher eukaryotic OST complexes contain one single binding site for the polypeptide substrate while it binds the LLO donor substrate in a cooperative manner. This property is only present in multi-subunit OST complexes that are expressed in organisms that assemble Dol-PP-GlcNAc₂Man₉Glc₃ LLOs (Karaoglu et al. 2001; Daniel J Kelleher et al. 2003; Kelleher et al. 2007). A substrate activation model was suggested where the binding of the LLO donor substrate to the regulatory LLO binding site is a prerequisite for the binding of both the polypeptide substrate and second LLO donor substrate to the catalytic site (Karaoglu et al. 2001). Furthermore, as it has been shown that two mammalian isoforms, *STT3A* and *STT3B* respectively, have distinct catalytic site kinetics but not the regulatory site kinetic parameters, it has been suggested that the regulatory site is provided by one or more of the non-catalytic subunits (Daniel J Kelleher et al. 2003; Kelleher et al. 2007). Albeit the identity of such subunit(s) has not been described thus far.

The suboptimal LLOs are responsible for the reduced rate of oligosaccharide transfer to nascent polypeptides, resulting in hypoglycosylation of proteins. Furthermore, protein bound oligosaccharide assembly intermediates are less efficiently glucosylated by the UDP-glucose glycoprotein glucosyltransferase (UGGT) enzyme, resulting in the inefficient glycoprotein quality control in the ER (ERQC), protein misfolding and targeting for ER-associated degradation (ERAD) (Trimble et al. 1980; Helenius & Aebi 2004). This is eminently evident in human CDGs (Hennet 2012). Considering the consequences mentioned, it is not surprising that cells have evolved ways to ensure the transfer of the fully assembled donor substrate to the asparagine site chains of nascent polypeptides.

Although there are still many questions to be answered, the findings of this thesis contribute a part towards the understanding of the mechanisms of protein N-linked glycosylation.

Curriculum vitae

Kristina Poljak

Personal information

Date of birth: 04.11.1987
Nationality: Croatian
Current address: Hohlstrasse 465, 8048 Zurich, Switzerland
E-mail: poljakk@ethz.ch

Education

05/2012 – present **PhD thesis**
Institute of Microbiology, ETH Zürich, Zürich, Switzerland

09/2009 – 07/2011 **MSc in Molecular Biology**
Department of Molecular Biology, Faculty of Science, University of Zagreb, Zagreb, Croatia

09/2009 – 07/2011 **MSc in Bioindustrial Techniques**
Department of Biology, Faculty of Science, University of Orléans, France

09/2006 – 07/2009 **BSc in Molecular Biology**
Department of Molecular Biology, Faculty of Science, University of Zagreb, Croatia

Research Experience

5/2012 – present **PhD training,**
ETH Zürich, Institute of Microbiology, Zürich, Switzerland

11/2011 – 5/2012 **Research assistant**
ETH Zürich, Institute of Microbiology, Zürich, Switzerland

02/2011 – 07/2011 **Diploma thesis**
*Centre de Biophysique Moléculaire (CBM) and Centre de Recherche sur la Matière Divisée (CRMD),
Centre National de la Recherche Scientifique (CNRS), Orléans, France*

10/2008 – 04/2010 **Research assistant**
*Department for Biochemistry and Molecular Biology, Faculty of Pharmacy and Biochemistry,
University of Zagreb, Croatia (awarded with Rector's Prize)*

02/2011 – 09/2009 **Semester Project**
Department for Biochemistry, Faculty of Science, University of Zagreb

Scholarships, Honours and Awards

12/2015	Best Oral Presentation award at Targeted Proteomics Conference, <i>Mumbai, India</i>
02/2015	MIM Travel grant for participation at Gordon Research Workshop and Conference, <i>Braga, Italy</i>
07/2010	Rector's Prize (Best Research Project), <i>Zagreb, Croatia</i>
09/2009 – 09/2010	Croatian National Foundation Scholarship for Gifted Students, <i>Zagreb, Croatia</i>
09/2006 – 09/2009	National scholarship of the Croatian Ministry of Science, <i>Zagreb, Croatia</i>
09/2002 – 06/2006	Scholarship of the City of Sinj, <i>Sinj, Croatia</i>

Publications

1. Mueller S, Wahlander A, Selevsek N, Otto C, Ngwa E, **Poljak K**, Frey AD, Aebi M and Gauss R (2015) *Protein degradation corrects for imbalanced subunit stoichiometry in OST complex assembly*. Mol Biol Cell. 2015 Jul 15; 26 (14): 2596-608
2. Naegeli A, Neupert C, Fan YY, Lin CW, **Poljak K**, Papini AM, Schwarz F and Aebi M (2014) *Molecular analysis of an alternative N-glycosylation machinery by functional transfer from Actinobacillus pleuropneumoniae to Escherichia coli*. J Biol Chem. 2014 Jan 24; 284 (4):2170-9

Language Skills

Mother tongue: Croatian

Fluent: English (written, oral)

Intermediate: German (written, oral), Spanish (written, oral)

Basic: French (written, oral), Italian (written, oral)
