The String Guessing Problem as a Method to Prove Lower Bounds on the Advice Complexity[☆]

Hans-Joachim Böckenhauer, Juraj Hromkovič, Dennis Komm, Sacha Krug, Jasmin Smula, Andreas Sprock

Department of Computer Science, ETH Zurich, Switzerland

Abstract

The advice complexity of an online problem describes the additional information both necessary and sufficient for online algorithms to compute solutions of a certain quality. In this model, an oracle inspects the input before it is processed by an online algorithm. Depending on the input string, the oracle prepares an advice bit string that is accessed sequentially by the algorithm. The number of advice bits that are read to achieve some specific solution quality can then serve as a fine-grained complexity measure. The main contribution of this paper is to study a powerful method for proving lower bounds on the number of advice bits necessary. To this end, we consider the string guessing problem as a generic online problem and show a lower bound on the number of advice bits needed to obtain a good solution. We use special reductions from string guessing to improve the best known lower bound for the online set cover problem and to give a lower bound on the advice complexity of the online maximum clique problem.

Keywords: Online algorithms, competitive analysis, advice complexity, online set cover, online clique

1. Introduction

Numerous computational problems work in so-called *online environments*, i. e., frameworks where the input arrives piecewise in successive time steps. An *online algorithm* has to answer every such piece by a part of the final output without knowing anything about the future requests (i. e., the rest of the input). In 1985, Sleator and Tarjan introduced the *competitive ratio* as a tool to measure the quality of such algorithms [21]. For an introduction to online computation and competitive analysis, we refer to the standard literature, e. g., [3].

In this paper, we study the model of *computing with advice* to analyze how much information is necessary and sufficient to enable online algorithms to improve over purely deterministic strategies. The idea is to consider an oracle that sees the whole input in advance and writes binary information about this

input onto an *advice tape* that may, at runtime, be accessed by the online algorithm. The idea of online computation with advice was introduced in [11]. Revised versions of this model were simultaneously introduced in [5, 15] and [12]. We follow the most general and exact model from [15] in this paper. The advice complexity was studied for various online problems in, e. g., [2, 4, 5, 6, 7, 9, 12, 13, 16, 17, 20].

Definition 1 (Online Algorithm with Advice [5, 15]). Let $I = (x_1, \dots, x_n)$ be an input of an online minimization problem. An *online algorithm A with advice* computes the output sequence $A^\phi(I) = (y_1, \dots, y_n)$ such that y_i is computed from ϕ, x_1, \dots, x_i , where ϕ is the content of the advice tape, i. e., an infinite binary sequence. For some output sequence o , $\text{cost}(o)$ denotes the cost of o . An online algorithm **A** is *c-competitive with advice complexity $b(n)$* if there is some non-negative constant α such that, for every n and for each input sequence I of length at most n , there is some ϕ such that $\text{cost}(A^\phi(I)) \leq c \cdot \text{cost}(\text{Opt}(I)) + \alpha$ and at most the first $b(n)$ bits of ϕ have been accessed during the computation of $A^\phi(I)$. Here, $\text{Opt}(I)$ denotes an optimal solution for I . If $\alpha = 0$, then **A** is called *strictly c-competitive*. Moreover, **A** is optimal if it is strictly 1-competitive. The definition for maximization problems is analogous.

The concept of advice complexity enables us to perform a much more fine-grained analysis of the hardness of online problems than using the classical competitive analysis. We are especially interested in *lower bounds* on the advice complexity. Such lower bounds not only tell us something about the information content [15] of online problems, but they also carry over to a randomized setting where they imply lower bounds on the number of random decisions needed to compute a good solution [16]. However, similar to most other computing models, also lower bounds on the advice complexity are hard to prove. Thus, it is desirable to have some generic proof methods to establish lower bounds. In this paper, we approach this goal by considering a generic online problem and showing how to transfer lower bounds on its advice complexity to lower bounds for other online problems.

1.1. Our Contribution and Related Work

We study the *string guessing problem* with respect to its advice complexity in Section 2. This problem is shown to be generic with respect to proving lower bounds on the advice complexity. Here, a string of length n over an alphabet of size q has to be guessed symbol by symbol. More specifically, we define two versions of the problem where, in the first case, the algorithm gets immediate feedback which decisions would have been correct up to the current time step, whereas, in the second case, this feedback is not supplied. First, we prove a lower bound on the advice necessary to achieve some specific number of correct guesses for both versions. Second, we analyze an upper bound on the size of the advice depending on both n and q .

Employing this result, we use reductions from the string guessing problem as a technique to prove lower bounds for other well-studied online problems. It seems to be a promising approach to take further steps in this direction and develop general methods to prove lower bounds on the advice complexity. Our first application, stated in Section 3, deals with an online version of the set cover problem as introduced in [1]. We show how to use the results on the

string guessing problem to give a lower bound that closes an exponential gap between the lower and upper bounds given in [17]. Second, in Section 4, we study an online version of the maximum clique problem where the vertices of the graph arrive consecutively. In every time step, an online algorithm has to decide whether the current vertex is part of the solution or not. We give a lower bound on the number of necessary advice bits that is linear in the number of vertices.

Note that Emek et al. [12] followed a similar approach to prove a lower bound on the advice complexity of randomized online algorithms with advice for metrical task systems. They defined a problem called *generalized matching pennies* (GMP), which is basically our string guessing problem with known history, but with a different, somewhat artificial cost function. This cost function depends on a parameter $\tau > 0$ such that any online algorithm for GMP pays at least $1/\tau$ in every time step. Any reduction from GMP depends on the concrete choice of τ . Moreover, their proof method only gives meaningful results for a number b of advice bits per time step that is bounded by $1 \leq b \leq \frac{1}{3} \log_2 q$, whereas our results cover the complete range $0 \leq b \leq \log_2 q$. (Note that $\log_2 q$ advice bits per time step obviously allow an algorithm to be optimal.) In particular, our model also works for $b \in o(1)$. Additionally, it allows to prove lower bounds for any alphabet size $q \geq 2$ and for any desired competitive ratio, whereas their lower bounds are limited to alphabets of size at least 4 and competitive ratios strictly less than 2. Overall, while their approach also works for randomized algorithms, considering only deterministic algorithms, our string guessing problem offers a more general, uniform, easy-to-use technique to prove lower bounds on the advice complexity of online problems.

2. The String Guessing Problem

In many online problems, the question arises whether knowing the history, i. e., the parts of an optimal solution that correspond to the input known at a specific time step, has an effect on the additional information necessary to achieve a certain competitive ratio. We deal with this question studying a very generic online problem, namely the string guessing problem. In the first variant, the algorithm has to guess a character from some fixed alphabet, then, in the next step, it is told what would have been the correct answer and is asked for the next character. In the second variant, the algorithm also has to guess character by character, but it gets no feedback about whether its answer was correct or not until the very end of the request sequence. In both cases, the length n of the string is given as the first request and the algorithm then has to guess n characters step by step.

In what follows, the *Hamming distance* between two strings of the same length denotes the number of positions at which these two strings differ. Let us begin by defining the two variants of the string guessing problem formally.

Definition 2 (String Guessing, Known History). The *string guessing problem with known history over an alphabet Σ of size $q \geq 2$* (q -SGKH) is the following online minimization problem. The input $I = (n, d_1, d_2, \dots, d_n)$ consists of a natural number n and the characters $d_1, d_2, \dots, d_n \in \Sigma$, that are revealed one by one. The online algorithm A computes the output sequence $A(I) = y_1 y_2 \dots y_n$, where $y_i = f(n, d_1, \dots, d_{i-1}) \in \Sigma$, for some computable function f . The algorithm is not required to respond with any output in the last time step. The

cost of a solution $\mathbf{A}(I)$ is the number of wrongly guessed characters, i.e., the Hamming distance $\text{Ham}(d, \mathbf{A}(I))$ between $d = d_1 d_2 \dots d_n$ and $\mathbf{A}(I)$.

Definition 3 (String Guessing, Unknown History). The *string guessing problem with unknown history over an alphabet Σ of size $q \geq 2$ (q -SGUH)* is the following online minimization problem. The input $I = (n, ?, ?, \dots, ?, d)$ consists of the input size n in the first request, $n - 1$ subsequent requests “?” carrying no extra information, and the correct string $d = d_1 \dots d_n \in \Sigma^n$. In each of the first n time steps, the online algorithm \mathbf{A} is required to output one character from Σ , forming the output sequence $\mathbf{A}(I) = y_1 y_2 \dots y_n$. As above, the algorithm is not required to respond with any output in the last time step, where the string d is revealed. The cost of a solution $\mathbf{A}(I)$ is again the Hamming distance between d and $\mathbf{A}(I)$.

For simplicity, we sometimes speak about the input string $d = d_1 d_2 \dots d_n$ when we mean the input sequence $I = (n, d_1, d_2, \dots, d_n)$ or $I = (n, ?, ?, \dots, ?, d)$ with $n = |d|$. Also, we write $\mathbf{A}(d)$ instead of $\mathbf{A}(I)$. Since the cost of an optimal solution for any string guessing instance is always 0, it is not meaningful to consider the competitive ratio as a measure for these problems. We therefore restrict our analysis to the number of errors produced by an algorithm. Our goal is to minimize this number.

It is easy to see that, for every deterministic online algorithm without advice, there is an input string of length n such that the algorithm produces n errors. This holds for any alphabet of arbitrary size $q \geq 2$. To see this, consider an adversary Adv that, in each time step, produces an input character α_i differing from the deterministic output $y_i = f(n, \alpha_1, \dots, \alpha_{i-1})$ of the algorithm. Clearly, no deterministic online algorithm gains anything by knowing the history.

Considering online algorithms with advice that produce optimal solutions, we easily see that each such algorithm needs to read at least $\lceil n \log_2 q \rceil$ advice bits to be optimal on any input of length n , even in the case of known history: Assume an optimal algorithm \mathbf{A} reads $m < \lceil n \log_2 q \rceil$ advice bits. There are q^n possible different input strings, but only

$$2^m \leq 2^{\lceil n \log_2 q \rceil - 1} < 2^{n \log_2 q} = q^n$$

different advice strings. Thus, at least two different input strings get the same advice. There is one position where these two strings differ for the first time. The algorithm \mathbf{A} makes a deterministic decision in the corresponding time step that is optimal for at most one of the two solutions and Adv can always choose the other one. A matching upper bound, even in the case of q -SGUH, can be achieved by simply enumerating all possible inputs and encoding the index of the concrete instance using $\lceil n \log_2 q \rceil$ advice bits.

On the other hand, a constant amount of advice can already help to guess a linear number of characters correctly, even without considering the history.

Observation 1. *There is an online algorithm for q -SGUH that guesses at least $\lceil n/q \rceil$ positions correctly on any input string of size n using $\lceil \log_2 q \rceil$ advice bits.*

PROOF. In every input string of length n over an alphabet of size q , at least one character z occurs at least $\lceil n/q \rceil$ times, and it can be specified by the oracle using $\lceil \log_2 q \rceil$ bits. An online algorithm that outputs z in every step guesses at least $\lceil n/q \rceil$ positions correctly. \square

In the remainder of this section, we estimate the number of advice bits necessary and sufficient to obtain a specific cost.

2.1. Lower Bounds

First, we show a lower bound on the number of advice bits necessary to guarantee that there is at most a specific number of wrong answers for q -SGUH. Consider an online algorithm A using b advice bits. This can be seen as a collection of 2^b different deterministic algorithms [17]. As all inputs look the same on the first n requests, the behavior of these algorithms can only depend on the advice.

For each of the q^n possible inputs, the oracle can choose between 2^b different algorithms, each of which produces a fixed output string. The oracle has to select a set of 2^b such strings, which we call *center strings*, in such a way that the maximum distance of any input string to the nearest of these center strings is minimized. This is exactly the task of constructing a so-called *covering code*. A covering code $K_q(n, r)$ over an alphabet Σ of size q of the strings of length n with radius r is defined as a set of codewords (elements of Σ^n) with the property that every string in Σ^n has a distance of at most r to at least one codeword in $K_q(n, r)$. For an overview of covering codes, we recommend [8]. The minimum size of a covering code $K_q(n, r)$ gives us the number of different advice strings we need to make sure that the worst-case error over all inputs for q -SGUH is at most r .

To get a simple lower bound on the size of a covering code $K_q(n, r)$, we consider the Hamming balls of radius r around the center strings. A Hamming ball of radius r around a string s in Σ^n consists of all strings t with Hamming distance $\text{Ham}(s, t) \leq r$. Due to the symmetry¹ of the hypercube, the size of a Hamming ball of radius r around some string s does not depend on s . Thus, we denote it by

$$\text{Vol}_q(n, r) = \sum_{i=0}^r \binom{n}{i} (q-1)^i.$$

To make sure that no error greater than r occurs for any input string, the number b of necessary advice bits has to satisfy the condition

$$q^n \leq 2^b \cdot \text{Vol}_q(n, r). \quad (1)$$

Let

$$H_q(p) = p \log_q(q-1) - p \log_q p - (1-p) \log_q(1-p)$$

denote the q -ary entropy function, for $0 < p < 1$. With this, $\text{Vol}_q(n, r)$ can be estimated as follows.

Lemma 1 (Guruswami et al. [14]). *Let $p \in \mathbb{R}$, $q \in \mathbb{N}^{>1}$, $0 < p \leq 1 - 1/q$. For sufficiently large n , we obtain $\text{Vol}_q(n, pn) \leq q^{H_q(p)n}$. \square*

¹The q^n strings of length n over an alphabet of size q can be seen as the vertices of a q -ary hypercube, which is known to be vertex-symmetric.

An easy calculation immediately yields

$$\text{Vol}_q(n, pn) \leq q^{H_q(p)n} = \left(\frac{q-1}{p}\right)^{pn} \left(\frac{1}{1-p}\right)^{(1-p)n}. \quad (2)$$

This observation leads to the following lower bound for q -SGUH.

Theorem 1. *Consider an input string of length n for q -SGUH, for some $n \in \mathbb{N}$. Any online algorithm that is correct in more than αn characters, for $1/q \leq \alpha < 1$, needs to read at least*

$$\left(1 + (1 - \alpha) \log_q \left(\frac{1 - \alpha}{q - 1}\right) + \alpha \log_q \alpha\right) n \log_2 q = (1 - H_q(1 - \alpha))n \log_2 q$$

advice bits.

PROOF. Guessing at least αn characters correctly means there can be at most $(1 - \alpha)n$ errors. We define $\alpha' = 1 - \alpha$ and substitute r by $\alpha'n$. Then we know from (1) that each algorithm that guarantees to make less than $\alpha'n$ errors uses at least b advice bits, where b satisfies

$$\frac{q^n}{2^b} \leq \text{Vol}_q(n, \alpha'n).$$

To give a lower bound on b , we apply (2), which yields

$$\begin{aligned} \frac{q^n}{2^b} &\leq \left(\frac{q-1}{\alpha'}\right)^{\alpha'n} \left(\frac{1}{1-\alpha'}\right)^{(1-\alpha')n} \\ \iff 2^b &\geq q^n \cdot \left(\frac{\alpha'}{q-1}\right)^{\alpha'n} \cdot (1-\alpha')^{(1-\alpha')n} \\ \iff b &\geq n \cdot \log_2 q + \alpha'n \cdot \log_2 \left(\frac{\alpha'}{q-1}\right) + (1-\alpha')n \cdot \log_2(1-\alpha') \\ \iff b &\geq n \cdot \log_2 q + \alpha'n \cdot \log_2 q \cdot \log_q \left(\frac{\alpha'}{q-1}\right) \\ &\quad + (1-\alpha')n \cdot \log_2 q \cdot \log_q(1-\alpha') \\ \iff b &\geq \left(1 + \alpha' \log_q \left(\frac{\alpha'}{q-1}\right) + (1-\alpha') \log_q(1-\alpha')\right) n \cdot \log_2 q. \end{aligned}$$

We now resubstitute α' by $1 - \alpha$ and obtain

$$b \geq \left(1 + (1 - \alpha) \log_q \left(\frac{1 - \alpha}{q - 1}\right) + \alpha \log_q \alpha\right) n \log_2 q.$$

Thus, we have established a lower bound on b to guarantee at least αn correct characters or, in other words, a maximal number of $\alpha'n$ errors. \square

The above argument heavily relies on the fact that, in case of q -SGUH, the output of a deterministic algorithm is unambiguously determined by the given advice. In the case of q -SGKH, this is no longer true. A deterministic algorithm might base its output on the history and thus might output different strings

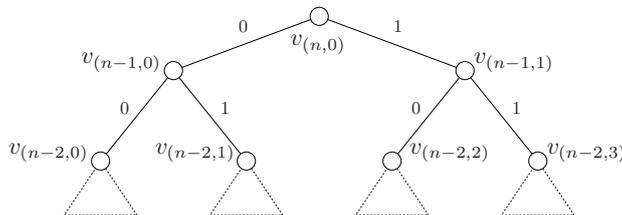

Figure 1: The tree T_n representing all input instances for $q = 2$.

while reading the same advice. In the following we show that, despite of this complication, the same lower bound as in Theorem 1 also holds for q -SGKH.

For the analysis, we use the q -ary tree T_n of depth n as a representation of the set Σ^n of all input strings of length n over the alphabet Σ (see Figure 1). For $0 \leq i \leq q^n - 1$, the leaf $v_{(0,i)}$ represents the i th string in lexicographic order in Σ^n and every inner vertex $v_{(h,i)}$, for $1 \leq h \leq n$, represents all 2^h strings of the leaves of the subtree rooted in $v_{(h,i)}$. Let A be an online algorithm for q -SGKH that uses at most b advice bits for any input instance of length n . Due to the pigeonhole principle, at least one advice string is used for at least $\lceil q^n / 2^b \rceil$ different input instances. For a given advice string ϕ of length b , we now take a closer look at the set \mathcal{I}_ϕ of input strings for which A gets the advice string ϕ . The algorithm A is not able to distinguish between any two strings in \mathcal{I}_ϕ at the beginning of the computation. However, this situation may change during the computation since A gets the additional information of what would have been the correct output in every time step so far.

We now investigate the maximal cardinality of \mathcal{I}_ϕ such that A can guarantee that the maximal number of errors is r . We can view every computation of an online algorithm as a path in T_n from the root down to a leaf. In every time step, the algorithm decides which subtree to enter. In the following step, it is revealed which direction would have been correct. If instances in more than one subtree of some vertex are represented by the given advice, the algorithm cannot know which subtree is correct.

For any vertex v in T_n , let $F(v)$ denote the maximal number of errors the adversary Adv can enforce in the remaining input string inside the subtree rooted at v , in addition to the errors already made on the way from the root to v . Moreover, let $\Psi: \mathbb{N} \times \mathbb{N} \rightarrow \mathbb{N}$ be a function such that $\Psi(h, r)$ measures how many strings in \mathcal{I}_ϕ can at most be represented by a vertex at depth h such that the enforceable number of errors is at most r . We are interested in the value $\Psi(n, r)$ which gives us the desired lower bound and can be computed as follows.

Lemma 2. *For $0 \leq r \leq h \leq n$, we have*

$$\Psi(h, r) = \sum_{i=0}^r \binom{h}{i} (q-1)^i = \text{Vol}_q(h, r).$$

PROOF. The function F can be computed recursively as follows. Let $v \in V$ be a vertex in T_n such that the subtree rooted at v contains at least one vertex that corresponds to a string from \mathcal{I}_ϕ and $\max\{F(u) \mid u \text{ is a child of } v\} = m$. Then,

$$F(v) = \begin{cases} m + 1 & \text{if there are at least two children } u, w \text{ with } F(u) = F(w) = m, \\ m & \text{else.} \end{cases} \quad (3)$$

To prove (3), we distinguish two cases. In the first case, there are two or more subtrees with the same maximal value of F . In the second case, there is exactly one subtree with a maximal number of errors.

Case 1. There are at least two children u and w of v with $F(u) = F(w) = m$. Thus, it does not matter which subtree the algorithm chooses, because Adv will choose another subtree with a maximal number of errors and thus enforce one error in the current time step as well as the m errors in the corresponding subtree.

Case 2. There is exactly one child u of v with $F(u) = m$ and, for all other children w of v , $F(w) < m$. The algorithm should choose the subtree rooted at u and accept m errors. Otherwise, Adv would choose the subtree rooted at u and thus enforce one error in the current time step and overall $m + 1$ errors in the subtree rooted in v .

This proves (3). We now show that the function $\Psi(h, r)$ satisfies the recurrence relation

$$\Psi(h, 0) = 1, \quad (4)$$

$$\Psi(h, h) = q^h, \text{ and} \quad (5)$$

$$\Psi(h, r) = \Psi(h - 1, r) + (q - 1) \cdot \Psi(h - 1, r - 1), \text{ for } 0 < r < h. \quad (6)$$

To prove (4), assume two input strings are represented by two leaves in T_h . These two leaves have a lowest common ancestor $v_{(g,j)}$, with $1 \leq g \leq h$. When the algorithm reaches $v_{(g,j)}$, it has to choose one of the q successors. It does not matter which subtree the deterministic algorithm takes, Adv can always choose another one, i. e., another possible input string, and hence enforce one error. Thus, $\Psi(h, 0) = 1$.

If h errors are allowed, it obviously does not matter what the algorithm does at depth h because, in the worst case, the algorithm makes one error per step and thus at most h errors in total. In other words, a subtree at depth h with h errors allowed can represent q^h strings, i. e., $\Psi(h, h) = q^h$, proving (5).

Additionally, we know from (3) that, for a vertex v at depth h with at most r enforceable errors, the maximal number of errors in all q subtrees of v cannot be larger than r . Furthermore, we know that no two subtrees can have an error of r . To maximize the number of errors in the subtree rooted at v , one child is assigned r errors and all others $r - 1$ errors. The maximal number of instances represented by a tree of depth h when r errors are allowed is thus

$$\Psi(h, r) = \Psi(h - 1, r) + (q - 1) \cdot \Psi(h - 1, r - 1),$$

which proves (6).

Using this recurrence, we are now able to prove the claim of this lemma by induction on h . We already know that $\Psi(1, 0) = 1 = \sum_{i=0}^0 \binom{1}{i} (q-1)^i$ and $\Psi(1, 1) = q = \sum_{i=0}^1 \binom{1}{i} (q-1)^i$. Now we prove the statement for $h > 1$ and $0 \leq r \leq h$.

As induction hypothesis, assume that $\Psi(h, r) = \sum_{i=0}^r \binom{h}{i} (q-1)^i$. Note that

$$\Psi(h+1, r) = \Psi(h, r) + (q-1) \cdot \Psi(h, r-1)$$

holds due to (6) and recall that $\binom{n}{k} + \binom{n}{k-1} = \binom{n+1}{k}$. We get

$$\Psi(h+1, r) = \Psi(h, r) + (q-1) \cdot \Psi(h, r-1)$$

which, by the induction hypothesis, leads to

$$\begin{aligned} \Psi(h+1, r) &= \sum_{i=0}^r \binom{h}{i} (q-1)^i + (q-1) \sum_{i=0}^{r-1} \binom{h}{i} (q-1)^i \\ &= \binom{h}{0} (q-1)^0 + \sum_{i=1}^r \binom{h}{i} (q-1)^i + \sum_{i=0}^{r-1} \binom{h}{i} (q-1)^{i+1} \\ &= \binom{h}{0} (q-1)^0 + \sum_{i=1}^r \binom{h}{i} (q-1)^i + \sum_{i=1}^r \binom{h}{i-1} (q-1)^i \\ &= \binom{h}{0} (q-1)^0 + \sum_{i=1}^r \left(\binom{h}{i} + \binom{h}{i-1} \right) (q-1)^i \\ &= \binom{h+1}{0} (q-1)^0 + \sum_{i=1}^r \binom{h+1}{i} (q-1)^i \\ &= \sum_{i=0}^r \binom{h+1}{i} (q-1)^i. \end{aligned}$$

It follows that

$$\Psi(h+1, h+1) = \sum_{i=0}^{h+1} \binom{h+1}{i} (q-1)^i = q^{h+1},$$

where the last equation holds due to the binomial theorem. With this, the claim follows for all values of $\Psi(h+1, r)$, for $0 \leq r \leq h+1$. \square

From Lemma 2 for $h = n$ together with Theorem 1, we immediately get the following lower bound on the advice complexity for q -SGKH. Note that this result coincides with the above lower bound for q -SGUH.

Theorem 2. *Consider an input string of length n for q -SGKH, for some $n \in \mathbb{N}$. Any online algorithm that is correct in more than αn characters, for $1/q \leq \alpha < 1$, needs to read at least*

$$\left(1 + (1 - \alpha) \log_q \left(\frac{1 - \alpha}{q - 1} \right) + \alpha \log_q \alpha \right) n \log_2 q = (1 - H_q(1 - \alpha)) n \log_2 q$$

advice bits. \square

For $q = 2$, i. e., for the *bit string guessing problem*, we get the following result.

Corollary 1. *Consider as input a bit string of length n for 2-SGKH. Every deterministic algorithm that can guarantee to be correct in more than αn bits, for $1/2 \leq \alpha < 1$, needs to read at least*

$$(1 + (1 - \alpha) \log_2(1 - \alpha) + \alpha \log_2 \alpha) n$$

many advice bits. □

2.2. Upper Bounds

To give an upper bound on the advice complexity of q -SGUH on strings of length n with at most r errors, we analyze the minimal size of a covering code of length n with radius r .

Lemma 3 (Moser and Scheder [19]). *Let $n \in \mathbb{N}^{>0}$, $q \in \mathbb{N}^{>1}$, $r \in \mathbb{N}$. Over any alphabet of size q , there is a covering code of length n with radius r of size at most*

$$\left\lceil \frac{n \cdot \ln q \cdot q^n}{\text{Vol}_q(n, r)} \right\rceil. \quad \square$$

To estimate an upper bound on the length of the advice string that is sufficient to guarantee a certain number of correct characters, we need a lower bound on the volume of the Hamming ball of radius r .

Lemma 4. *Let $p \in \mathbb{R}$, $q \in \mathbb{N}^{>1}$, $0 < p \leq 1 - 1/q$, such that $pn \in \mathbb{N}$. For sufficiently large n ,*

$$\text{Vol}_q(n, pn) \geq q^{H_q(p) \cdot n - \frac{1}{2} \log_q(2n)}.$$

PROOF. We know from [18] that

$$\binom{n}{pn} \geq \frac{1}{\sqrt{8np(1-p)}} \cdot 2^{H_2(p) \cdot n}.$$

It follows that

$$\begin{aligned} \text{Vol}_q(n, pn) &= \sum_{i=0}^{pn} \binom{n}{i} (q-1)^i \\ &\geq \binom{n}{pn} \cdot (q-1)^{pn} \\ &\geq \frac{1}{\sqrt{8np(1-p)}} \cdot 2^{H_2(p) \cdot n} \cdot (q-1)^{pn}. \end{aligned}$$

Together with the simple fact that $2^{H_2(p) \cdot n} \cdot (q-1)^{pn} = q^{H_q(p) \cdot n}$, we get

$$\text{Vol}_q(n, pn) \geq \frac{q^{H_q(p) \cdot n}}{\sqrt{8np(1-p)}} \geq \frac{q^{H_q(p) \cdot n}}{\sqrt{2n}} = q^{H_q(p) \cdot n - \frac{1}{2} \log_q(2n)}. \quad \square$$

Now we are ready to prove an upper bound on the number of advice bits sufficient to guarantee more than αn correctly guessed characters.

Theorem 3. Consider an input of length n for q -SGUH, for some $n \in \mathbb{N}$. There is an online algorithm that is correct in more than αn characters, for $1/q \leq \alpha < 1$, and needs at most

$$\left\lceil (1 - H_q(1 - \alpha)) n \log_2 q + \frac{3}{2} \log_2 n + \log_2(\ln q) + \frac{1}{2} \right\rceil$$

many advice bits.

PROOF. Guessing at least αn characters correctly means there can be at most $\alpha' n$ errors for $\alpha' = 1 - \alpha$. To guarantee that there are at most $\alpha' n$ errors, we need to cover the strings of Σ^n with Hamming balls of radius at most $\alpha' n$. We know from Lemma 3 that there is such a covering with at most

$$\left\lceil \frac{n \cdot \ln q \cdot q^n}{\text{Vol}_q(n, \alpha' n)} \right\rceil$$

balls, which leads to an algorithm that can guarantee that there are at most $\alpha' n$ errors and that uses b advice bits such that b is the smallest integer satisfying

$$2^b \geq \left\lceil \frac{n \cdot \ln q \cdot q^n}{\text{Vol}_q(n, \alpha' n)} \right\rceil. \quad (7)$$

From Lemma 4, we know that

$$\begin{aligned} \text{Vol}_q(n, \alpha' n) &\geq q^{H_q(\alpha') \cdot n - \frac{1}{2} \log_q(2n)} \\ &\stackrel{(2)}{\geq} \left(\frac{q-1}{\alpha'} \right)^{\alpha' n} \left(\frac{1}{1-\alpha'} \right)^{(1-\alpha')n} \cdot \frac{1}{\sqrt{2n}}. \end{aligned}$$

Thus, it is sufficient for b to satisfy

$$\begin{aligned} \frac{n \cdot \ln q \cdot q^n}{2^b} &\leq \left(\frac{q-1}{\alpha'} \right)^{\alpha' n} \cdot \left(\frac{1}{1-\alpha'} \right)^{(1-\alpha')n} \cdot \frac{1}{\sqrt{2n}} \\ \Leftrightarrow 2^b &\geq \left(\frac{\alpha'}{q-1} \right)^{\alpha' n} \cdot (1-\alpha')^{(1-\alpha')n} \cdot \sqrt{2n} \cdot n \cdot \ln q \cdot q^n \\ \Leftrightarrow b &\geq \alpha' n \cdot \log_2 \left(\frac{\alpha'}{q-1} \right) + (1-\alpha')n \cdot \log_2(1-\alpha') \\ &\quad + \frac{1}{2} \cdot \log_2(2n) + \log_2 n + \log_2(\ln q) + n \cdot \log_2 q \\ \Leftrightarrow b &\geq \alpha' n \cdot \log_2 q \cdot \log_q \left(\frac{\alpha'}{q-1} \right) \\ &\quad + (1-\alpha')n \cdot \log_2 q \cdot \log_q(1-\alpha') \\ &\quad + \frac{1}{2} + \frac{1}{2} \log_2 n + \log_2 n + \log_2(\ln q) + n \cdot \log_2 q \\ \Leftrightarrow b &\geq \left(1 + \alpha' \log_q \left(\frac{\alpha'}{q-1} \right) \right. \\ &\quad \left. + (1-\alpha') \log_q(1-\alpha') \right) n \cdot \log_2 q \\ &\quad + \frac{3}{2} \log_2 n + \log_2(\ln q) + \frac{1}{2} \end{aligned}$$

We now resubstitute α' by $1 - \alpha$ and finally get

$$b \geq \left(1 + (1 - \alpha) \log_q \left(\frac{1 - \alpha}{q - 1}\right) + \alpha \log_q \alpha\right) n \log_2 q + \frac{3}{2} \log_2 n + \log_2(\ln q) + \frac{1}{2}.$$

Since we wanted to find the minimum value for b such that (7) is satisfied, we choose

$$b = \left\lceil \left(1 + (1 - \alpha) \log_q \left(\frac{1 - \alpha}{q - 1}\right) + \alpha \log_q \alpha\right) n \log_2 q + \frac{3}{2} \log_2 n + \log_2(\ln q) + \frac{1}{2} \right\rceil.$$

Hence, we now have an upper bound on the number b of advice bits necessary for an algorithm to guarantee at least αn correctly guessed characters. \square

For the special case of bit strings, we get the following result.

Corollary 2. *Consider as input a bit string of length n for 2-SGKH. There is an online algorithm reading at most*

$$\left\lceil \left(1 + (1 - \alpha) \log_2(1 - \alpha) + \alpha \log_2 \alpha\right) n + \frac{3}{2} \log_2 n + \frac{1}{2} + \log_2(\ln 2) \right\rceil$$

advice bits and that is correct in more than αn bits, for $1/2 \leq \alpha < 1$. \square

3. The Online Set Cover Problem

In this section, we study the advice complexity of the unweighted online set cover problem, which was introduced in [1] and is defined as follows.

Definition 4 (Online Set Cover Problem). Let $X = \{1, \dots, n\}$ be a *ground set* of size n , $X' \subseteq X$ a set of *requests*, and $\mathcal{S} \subseteq \mathcal{P}(X)$ a set family of size m . Without loss of generality, no set in \mathcal{S} is the subset of another set in \mathcal{S} . The set X and the family \mathcal{S} are known beforehand, but the elements of X' arrive one by one in consecutive time steps. Thus, each instance of the *online set cover problem* (SETCOVER) corresponds to some subset $X' \subseteq X$ and a permutation of X' . Any subset $\{S_1, \dots, S_h\}$ of \mathcal{S} such that $\bigcup_{i=1}^h S_i \supseteq X'$ is a feasible solution for such an instance. The aim is to minimize h , i. e., to use as few sets as possible. An online algorithm **A** solves SETCOVER if, immediately after each yet uncovered request j , it specifies a set $S_i \in \mathcal{S}$ in the following way. If the request j is already covered, **A** chooses an arbitrary set S_i that it already chose in one of the previous rounds and that contains j . If j is not covered yet, **A** chooses a new set S_i with $j \in S_i$.

First, we observe that there is a reduction from q -SGKH to SETCOVER.

Theorem 4. *Assume an online algorithm **A** solves SETCOVER with b advice bits making at most r errors, i. e., choosing at most r sets more than an optimal algorithm. Then, there is an online algorithm **B** that solves the string guessing problem with known history with b advice bits and at most r errors.*

PROOF. First, we show how to transform an instance I_B for q -SGKH over an alphabet Σ of size q into an instance I_A for SETCOVER. Let the considered instance for q -SGKH be $I_B = (k, d_1, \dots, d_k)$. Hence, the input string $d = d_1 \dots d_k$ has length k . We give the set X and the family \mathcal{S} , which are known to the SETCOVER algorithm, depending on k and Σ . We set

$$X = \{X_t \mid t \text{ is a string over } \Sigma \text{ of length at most } k\}.$$

Hence, X contains $\sum_{i=0}^k q^i = (q^{k+1} - 1)/(q - 1)$ elements. Furthermore, $\mathcal{S} = \{\text{tr}(s) \mid s = s_1 \dots s_k \in \Sigma^k\}$, where

$$\text{tr}(s) = \{X_t \mid t \text{ is a prefix of } s\} = \{X_\lambda, X_{s_1}, X_{s_1 s_2}, \dots, X_{s_1 \dots s_k}\}$$

is the *transformation* of the string s and λ denotes the empty string. Each set $\text{tr}(s)$ contains $k + 1$ elements, and \mathcal{S} consists of q^k sets.

It remains to show that, in each time step j , we can transform the j th request of the q -SGKH instance into a request of the SETCOVER instance, and that we can also transform the output of a SETCOVER algorithm **A** into an output of a q -SGKH algorithm **B** such that the following condition is satisfied: If **A** uses b advice bits and makes at most r errors, then **B** also uses only b advice bits and makes at most r errors.

The request for **B** in time step $2 \leq j \leq k + 1$ consists of the character d_{j-1} . Hence, by time step j , algorithm **B** is aware of the first $j - 1$ characters $d_1 \dots d_{j-1}$ of the correct string. Then, the element that is requested to be covered by the SETCOVER algorithm **A** in time step j will be $X_{d_1 \dots d_{j-1}}$. Note that by this, **A** is implicitly informed about which character would have been the right choice in time step $j - 1$. The element $X_{d_1 \dots d_{j-1}}$ might already be covered, namely if **A** already chose a set $S_i = \text{tr}(s)$ for some string s with prefix $d_1 \dots d_{j-1}$ in one of the previous time steps. Then, according to Definition 4, the algorithm **A** picks one such previously chosen set now. If, on the other hand, $X_{d_1 \dots d_{j-1}}$ is not covered yet, **A** has to choose a new set containing $X_{d_1 \dots d_{j-1}}$ now. Since every set S_i corresponds to a certain string $s \in \Sigma^k$, the choice of a set containing element $X_{d_1 \dots d_{j-1}}$ corresponds to guessing all the remaining characters of the string d , in particular the character d_j . If, in time step j , **A** chooses a set S_i containing the element $X_{d_1 \dots d_{j-1} y_j}$, the string guessing algorithm **B** will output the character y_j as its guess for the j th character of d .

If **B** makes an error in time step $j - 1$, its guess in this time step is y_{j-1} for some character $y_{j-1} \neq d_{j-1}$. Then, the set S chosen by **A** in time step $j - 1$ must have been one containing the element $X_{d_1 \dots d_{j-2} y_{j-1}}$, and thus, S cannot contain $X_{d_1 \dots d_{j-1}}$. Hence, **A** made an error in time step $j - 1$. This error will be noticed by **A** in time step j , when it gets the request $X_{d_1 \dots d_{j-1}}$, and it has to pick a new set to cover this element. If **B** does not make an error in time step $j - 1$, **B** guesses d_{j-1} correctly, which means that **A** must have picked a set S containing $X_{d_1 \dots d_{j-2} d_{j-1}}$ in time step $j - 1$. The request sent to **A** in time step j is exactly this element $X_{d_1 \dots d_{j-2} d_{j-1}}$, and hence, **A** did not make an error in time step $j - 1$. Because the request sent to **A** in time step j is already covered, **A** does not choose an additional set in this time step.

All in all, we have shown that the string guessing algorithm **B** makes an error in time step j if and only if the SETCOVER algorithm **A** makes an error in time step j and has to pick a new set in time step $j + 1$. \square

The reduction above helps us to establish a lower bound on the advice complexity of SETCOVER. First, we show that it is equally hard to guess a percentage of α characters over one string of length rk as to guess the same percentage over r strings of length k over an alphabet of the same size. We start by formally defining the problem of guessing r strings of size k .

Definition 5 ((q, ℓ, k)-Multiple String Guessing, Known History). The (q, ℓ, k)-multiple string guessing problem with known history over an alphabet Σ of size $q \geq 2$ ((q, ℓ, k)-MULTISGKH for short) is to solve ℓ instances I_1, \dots, I_ℓ of q -SGKH of length k over an alphabet of size q . The input I is the concatenation of I_1, \dots, I_ℓ . The cost of a solution $\mathbf{A}(I)$ is the sum of the costs on the ℓ consecutive q -SGKH instances, i. e., $\text{cost}(\mathbf{A}(I)) = \sum_{i=1}^{\ell} \text{cost}(\mathbf{A}(I_i))$.

The following lemma states that as many advice bits are necessary to correctly guess $\alpha \ell k$ characters of a string of length ℓk over an alphabet of size q as to correctly guess $\alpha \ell k$ characters of an instance for (q, ℓ, k)-MULTISGKH.

Lemma 5. *Assume an online algorithm \mathbf{A} solves (q, ℓ, k)-MULTISGKH with b advice bits and makes r errors. Then there is also an online algorithm \mathbf{B} for q -SGKH on strings of length ℓk using b advice bits and making r errors.*

PROOF. Consider a q -SGKH instance of length ℓk . The first k requests of this instance get mapped to the k characters of the first string of a (q, ℓ, k)-MULTISGKH instance, and so on. Then, the decisions of an algorithm \mathbf{A} for (q, ℓ, k)-MULTISGKH can directly be used by an algorithm \mathbf{B} for q -SGKH on the corresponding positions. It is obvious that \mathbf{B} makes an error if and only if \mathbf{A} makes an error. \square

Theorem 5. *Let $q \in \mathbb{N}^{\geq 2}$. For any $k \in \mathbb{N}^{\geq 1}$ and any $c \in \mathbb{R}^{> 1}$, $c \leq 1 + k(1 - 1/q)$, every c -competitive online algorithm for SETCOVER needs to read*

$$\begin{aligned} b &\geq \left(1 + \frac{c-1}{k} \cdot \log_q \left(\frac{c-1}{k(q-1)}\right) + \frac{k-c+1}{k} \cdot \log_q \left(\frac{k-c+1}{k}\right)\right) \cdot \frac{k \cdot \log_2 q}{q^k} \cdot m \\ &= \left(1 - H_q \left(\frac{c-1}{k}\right)\right) \cdot \frac{k \cdot \log_2 q}{q^k} \cdot m \end{aligned}$$

or

$$\begin{aligned} b &\geq \left(1 + \frac{c-1}{k(q-1)} \cdot \log_q \left(\frac{c-1}{k}\right) + \frac{k-c+1}{k} \cdot \log_q \left(\frac{k-c+1}{k}\right)\right) \frac{k \cdot (q-1) \cdot \log_2 q}{q^{k+1}-1} \cdot n \\ &= \left(1 - H_q \left(\frac{c-1}{k}\right)\right) \frac{k \cdot (q-1) \cdot \log_2 q}{q^{k+1}-1} \cdot n \end{aligned}$$

advice bits, depending on whether we measure in $m = |\mathcal{S}|$ or in $n = |X|$.

PROOF. To prove the claim, we give a reduction from (q, ℓ, k)-MULTISGKH. Consider a set $\{s_1, \dots, s_\ell\}$ of ℓ strings of length k each over an alphabet of size q and the corresponding instance $I = (I_{s_1}, \dots, I_{s_\ell})$ of (q, ℓ, k)-MULTISGKH. We use the construction from the proof of Theorem 4 to construct ℓ SETCOVER instances (X_j, \mathcal{S}_j) from I_{s_j} such that the sets X_j (and thus also the set families \mathcal{S}_j) are pairwise disjoint. For each I_{s_j} , we also construct a sequence I'_{s_j} of requests for SETCOVER using the transformation from the proof of Theorem 4. Then we join these subinstances to get a SETCOVER instance (X, \mathcal{S}) by setting $X = \bigcup_{i=1}^{\ell} X_i$

and $\mathcal{S} = \bigcup_{i=1}^{\ell} \mathcal{S}_i$. The order of the requests in the SETCOVER instance follows an arbitrary order of the I_{s_j} , say $I_{s_1}, I_{s_2}, \dots, I_{s_\ell}$.

The constructed SETCOVER instance has an optimal solution of size ℓ since every subinstance has a solution of size 1 and all subinstances are disjoint. The size of the ground set is $(q^{k+1} - 1)/(q - 1) \cdot \ell = n$ and the size of the set family is $q^k \cdot \ell = m$. We know from Theorem 4 that, for each algorithm for SETCOVER that reads b advice bits and makes r errors, there is an algorithm B for q -SGKH using the same advice and making the same number of errors. Consider an algorithm A for the constructed SETCOVER instance that defines ℓ algorithms A_1, \dots, A_ℓ for instances of length k . Each of these algorithms corresponds to one particular subinstance (X_j, \mathcal{S}_j) of SETCOVER. Since these subinstances are disjoint, for any algorithm A_j that makes r_j errors while using b_j advice bits, there is an algorithm B_j using b_j advice bits that makes the same number of errors for the string s_j of the given instance of (q, ℓ, k) -MULTISGKH. Thus, in total, the number of errors A makes is the same as the number of errors made by some algorithm B for the whole (q, ℓ, k) -MULTISGKH instance. Due to Lemma 5, there is an algorithm C that makes r errors while reading b advice bits for any instance of q -SGKH.

The competitive ratio achieved by A is thus

$$c = \frac{\ell + (1 - \alpha) \cdot \ell k}{\ell} = 1 + (1 - \alpha) \cdot k,$$

hence $\alpha = 1 - (c - 1)/k$, where α denotes the fraction of correct answers. Since we assume $c \leq 1 + k(1 - 1/q)$, which implies $1/q \leq \alpha$, we can directly apply Theorem 2 yielding that

$$\begin{aligned} b &\geq \left(1 + \left(\frac{c-1}{k}\right) \log_q \left(\frac{c-1}{k(q-1)}\right) + \left(\frac{k-c+1}{k}\right) \log_q \left(\frac{k-c+1}{k}\right)\right) \cdot \ell k \cdot \log_2 q \\ &= \left(1 - H_q \left(\frac{c-1}{k}\right)\right) \cdot \ell k \cdot \log_2 q \end{aligned}$$

advice bits are necessary to be c -competitive. To measure in $|\mathcal{S}| = m$ and in $|X| = n$, we calculate $\ell = m/q^k$, and $\ell = (q - 1) \cdot n/(q^{k+1} - 1)$, and the claim follows. \square

From Lemma 5, we know that guessing a string of length ℓ is as hard as guessing ℓ strings of length 1. Thus, setting $k = 1$ and $q = 2$ (i. e., we consider 2-SGKH), Theorem 5 gives the following result, where $\ell = n/3 = m/2$ in the above proof.

Corollary 3. *For $c \leq 1.5$, any c -competitive online algorithm for SETCOVER needs to read*

$$b \geq (1 + (c - 1) \log_2(c - 1) + (2 - c) \log_2(2 - c)) \frac{n}{3}$$

or

$$b \geq (1 + (c - 1) \log_2(c - 1) + (2 - c) \log_2(2 - c)) \frac{m}{2}$$

advice bits, respectively. \square

Figure 2 shows lower bounds that are obtained using Theorem 5 for $k = 1$ and different values of q .

Note that, in [17], a lower bound on achieving a constant competitive ratio was shown that is merely logarithmic in m . Thus, Theorem 5 yields an exponential improvement over the best previously known result.

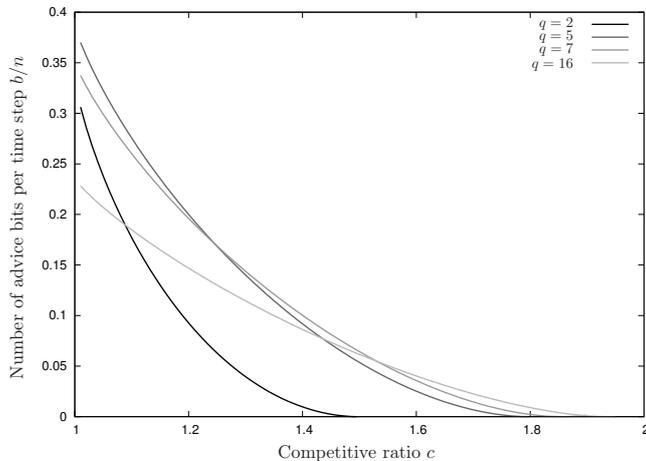

Figure 2: The number of advice bits necessary per time step for the online set cover problem.

4. The Online Maximum Clique Problem

In this section, we analyze the *online maximum clique* problem [10]. Here, in every time step, a vertex of a graph is given together with all edges to vertices that were already revealed in previous steps, and an online algorithm A has to decide whether the newly revealed vertex becomes part of the solution.

For giving a reasonable gain function, we briefly give some considerations. First, assume the input graph G has a maximum clique of size n and the algorithm finds a clique of size $n - 1$. Then, intuitively, the gain of the solution should be $n - 1$, irrespective of how many vertices of the found clique are also part of a largest clique in G . On the other hand, assume the algorithm selects a vertex that is not connected to any vertex revealed afterwards. Unless this is the only vertex A takes, A does not output a clique (i. e., its solution is not feasible). To avoid this, it should be allowed to give an output where not all selected vertices are part of a clique, different to the situation in [10]. Even if A gives an output in which many vertices form a large or even a maximum clique, but one additional vertex is selected such that the output is no clique, it is very close to a relatively good or even optimal solution. Thus, this solution should have almost optimal gain. Then again, we should clearly prevent the algorithm from simply selecting all vertices that are given. For an output $A(I)$, we therefore consider not only its size, but also the maximum clique $C_{A(I)}$ in the graph $G_{A(I)}$ restricted to the selected vertices $A(I)$. Then, the solution becomes better the larger the maximum clique in $G_{A(I)}$ is, and it becomes worse as more vertices are selected that are not part of $C_{A(I)}$. All in all, we propose the gain function given in the following definition.

Definition 6 (Online Maximum Clique Problem). The *online maximum clique problem* (MAXCLIQUE) is the following online problem. The input is a graph $G = (V, E)$ and the goal is to find a clique $C \subseteq V$ in G of maximum size. In each time step i , one vertex $v_i \in V$ is revealed together with all edges $\{\{v_i, v_j\} \in E \mid j < i\}$, and an online algorithm A has to decide whether $v_i \in C$ or not. Let $A(I)$ be the set of vertices selected by A , and let $C_{A(I)}$

be a maximum clique in the graph $G_{\mathbf{A}(I)}$. The gain function is defined by $\text{gain}(\mathbf{A}(I)) = |C_{\mathbf{A}(I)}|^2/|\mathbf{A}(I)|$.

Clearly, for the optimal solution $\mathbf{Opt}(I)$ of a graph with a maximum clique C_{opt} , we have

$$\text{gain}(\mathbf{Opt}(I)) = \frac{|C_{\text{opt}}|}{|\mathbf{Opt}(I)|} \cdot |C_{\text{opt}}| = |C_{\text{opt}}|,$$

thus, the competitive ratio of \mathbf{A} on I is

$$c = \frac{\text{gain}(\mathbf{Opt}(I))}{\text{gain}(\mathbf{A}(I))} = \frac{|\mathbf{A}(I)|}{|C_{\mathbf{A}(I)}|} \cdot \frac{|C_{\text{opt}}|}{|C_{\mathbf{A}(I)}|}.$$

In other words, the quality of the output of \mathbf{A} is given by the product of the two ratios $|\mathbf{A}(I)|/|C_{\mathbf{A}(I)}|$ and $|C_{\text{opt}}|/|C_{\mathbf{A}(I)}|$. The first ratio measures how many useless vertices \mathbf{A} has taken and the second ratio measures how many correct vertices \mathbf{A} has not taken.

In order to give a lower bound on the advice complexity of MAXCLIQUE , we use our results for 2-SGKH . To this end, we investigate the following subclass of instances, where every instance corresponds to a particular bit string. Let $s = s_1 s_2 \dots s_{n'}$ be a bit string of length n' , for some $n' \in \mathbb{N}$. We construct an input instance I_s for MAXCLIQUE corresponding to s as follows. Consider the graph $G_{I_s} = (V(I_s), E(I_s))$ with $n = 2n' + 2$ vertices. Let

$$V(I_s) = \{v_{(1,0)}, v_{(1,1)}, \dots, v_{(n'+1,0)}, v_{(n'+1,1)}\},$$

and let $V'(I_s) = \{v_{(i,s_i)} \mid 1 \leq i \leq n'\}$ be the set of the n' vertices that correspond to the string s . Moreover, let

$$\begin{aligned} E(I_s) = & \{ \{v_{(i,s_i)}, v_{(j,k)}\} \mid 1 \leq i < j \leq n', k \in \{0,1\} \} \\ & \cup \{ \{v, v_{(n'+1,0)}\}, \{v, v_{(n'+1,1)}\} \mid v \in V'(I_s) \} \\ & \cup \{ \{v_{(n'+1,0)}, v_{(n'+1,1)}\} \}. \end{aligned}$$

Clearly, the vertices from $V'(I_s)$ plus the vertices $v_{(n'+1,0)}$ and $v_{(n'+1,1)}$ form a unique optimal solution for I_s of size $n' + 2$. Although the vertices $v_{(i,0)}$ and $v_{(i,1)}$ are revealed separately (and after each vertex, the algorithm has to respond immediately), for the analysis, we combine them into one pair. After the first pair is revealed, the vertices of the second pair ($v_{(2,0)}, v_{(2,1)}$) are given, and so on. An example for the string 00101 of length 5 is given in Figure 3.

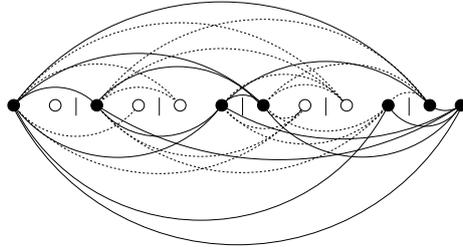

Figure 3: Example of the graph G_{00101} .

Assume that \mathbf{A} knows that one vertex of each pair is part of the optimal solution. Then, we can see MAXCLIQUE as guessing one vertex per pair. Similar to guessing a string s , also when trying to find the correct vertex in a pair $(v_{(i,0)}, v_{(i,1)})$ in G_{I_s} , the correct decision can only depend on the input known so far, the history, and the given advice. However, in general, an algorithm has four options for every pair that is revealed, which are to take only the first vertex, only the second one, both, or none. As a next step, we show that, for any online algorithm with advice, it is the best strategy to take both vertices of any pair for which no advice is used. In this way, we derive an upper bound on the gain of any online algorithm for MAXCLIQUE that uses at most b advice bits.

Lemma 6. *Let \mathbf{B} denote a best online algorithm with advice for 2-SGKH that reads b advice bits, and let s be any 2-SGKH instance of length n' . Let the number of bits of s that \mathbf{B} guesses correctly be at most $\alpha n'$, where $0 \leq \alpha \leq 1$. Then, no online algorithm \mathbf{A} for the corresponding MAXCLIQUE instance I_s reads b advice bits and achieves*

$$\text{gain}(\mathbf{A}(I_s)) > \frac{(\alpha n' + (1 - \alpha)n' + 2)^2}{\alpha n' + 2(1 - \alpha)n' + 2}.$$

Furthermore, an online algorithm \mathbf{A}^ that correctly guesses the same pairs as \mathbf{A} and takes both vertices for all remaining pairs satisfies $\text{gain}(\mathbf{A}^*(I_s)) \geq \text{gain}(\mathbf{A}(I_s))$.*

PROOF. First we prove by a reduction from the string guessing problem that no algorithm for MAXCLIQUE can correctly guess more than $\alpha n'$ pairs when using at most b advice bits. Consider any algorithm \mathbf{A} for MAXCLIQUE such that $\tilde{\alpha} n'$ is the number of pairs $(v_{(i,0)}, v_{(i,1)})$ of vertices in G_{I_s} that \mathbf{A} guessed correctly. For the sake of a contradiction, suppose $\tilde{\alpha} > \alpha$ and consider the following reduction to solve 2-SGKH with $\tilde{\alpha} n'$ correctly guessed bits. Every time step in 2-SGKH can be transformed into two time steps of MAXCLIQUE as described above. We then create an online algorithm \mathbf{A}' for 2-SGKH as follows. According to the output of \mathbf{A} in the two time steps that are associated with one pair, \mathbf{A}' gives the output 0 if \mathbf{A} takes the first vertex and 1 otherwise. Thus, \mathbf{A}' is an online algorithm with advice for 2-SGKH that guesses more than $\alpha n'$ bits correctly while using b advice bits and that is hence strictly better than \mathbf{B} , which is a contradiction to our assumption.

It follows that $\tilde{\alpha} \leq \alpha$. We may thus assume that \mathbf{A} guesses at most $\alpha n'$ pairs correctly for MAXCLIQUE, which is, by the above reasoning, the best \mathbf{A} can do. Additionally, we may assume that \mathbf{A} also knows where these $\alpha n'$ pairs lie in the instance I_s . For the rest of the $(1 - \alpha)n'$ requests, suppose that \mathbf{A} takes, for a fraction of β , both vertices of the corresponding pair, for a fraction of γ , the wrong one, and, for the remainder, no vertex at all. Thus, \mathbf{A} outputs a solution of size $\alpha n' + 2 + 2(1 - \alpha)\beta n' + (1 - \alpha)\gamma n'$, while $G_{\mathbf{A}(I_s)}$ has a clique $C_{\mathbf{A}(I_s)}$ of size $\alpha n' + 2 + (1 - \alpha)\beta n'$, yielding

$$\text{gain}(\mathbf{A}(I_s)) = \frac{(\alpha n' + 2 + (1 - \alpha)\beta n')^2}{\alpha n' + 2 + (1 - \alpha)(2\beta + \gamma)n'}.$$

We immediately observe that this term does not depend on the number of pairs for which \mathbf{A} chooses no vertex and that it decreases with increasing γ . We

therefore set γ to 0 and verify that the remaining term increases with β . To this end, let us substitute $X = \alpha n' + 2$ and $Y = (1 - \alpha)n'$ and consider the function

$$f(\beta) = \frac{(\alpha n' + 2 + (1 - \alpha)\beta n')^2}{\alpha n' + 2 + (1 - \alpha)2\beta n'} = \frac{(X + Y\beta)^2}{X + 2Y\beta}.$$

Since

$$f'(\beta) = \frac{2Y(X + Y\beta)(X + 2Y\beta) - 2Y(X + Y\beta)^2}{(X + 2Y\beta)^2}$$

is positive for all values of α and β between 0 and 1, we may set β to 1. In other words, the best algorithm \mathbf{A}^* that makes the right decisions on exactly the same set of pairs as \mathbf{A} takes both vertices for all remaining pairs. \square

In order to give a lower bound on the advice complexity, we analyze an online algorithm with advice that gets a sufficiently large number of advice bits to know $\alpha n'$ pairs and, following Lemma 6, takes both vertices for all unknown positions. Using our results from Section 2, we can prove the following theorem.

Theorem 6. *Any $(c - \varepsilon)$ -competitive online algorithm \mathbf{A} for MAXCLIQUE needs at least*

$$(1 + (c - 1) \log_2(c - 1) + (2 - c) \log_2(2 - c)) \frac{n - 2}{2} = (1 - H_2(c - 1)) \frac{n - 2}{2}$$

advice bits, for any $1 < c \leq 1.5$ and $\varepsilon > 0$.

PROOF. Let $n' = (n - 2)/2$. As above, assume that \mathbf{A} reads a sufficiently large number of advice bits to correctly guess $\alpha n'$ pairs. In order to give a lower bound, we again assume that \mathbf{A} also knows where these $\alpha n'$ pairs lie in the instance and that, according to Lemma 6, \mathbf{A} takes both vertices for all pairs where the corresponding bit is unknown. Thus,

$$\text{gain}(\mathbf{A}(I)) = \frac{(\alpha n' + 2 + (1 - \alpha)n')^2}{\alpha n' + 2 + 2(1 - \alpha)n'} = \frac{n'^2 + 2n' + 4}{2n' - \alpha n' + 2} = \frac{n' + 2 + \frac{4}{n'}}{2 - \alpha + \frac{2}{n'}}.$$

For the competitive ratio, we therefore get

$$c = \frac{\text{gain}(\text{Opt}(I))}{\text{gain}(\mathbf{A}(I))} = \frac{(n' + 2)(2 - \alpha + \frac{2}{n'})}{n' + 2 + \frac{4}{n'}} > \frac{n'(2 - \alpha)}{n' + 2 + \frac{4}{n'}} = \frac{2 - \alpha}{1 + \frac{2}{n'} + \frac{4}{n'^2}}.$$

For any α and any $\varepsilon > 0$, we have

$$c > \frac{(2 - \alpha)}{1 + \frac{2}{n'} + \frac{4}{n'^2}} \geq 2 - \alpha - \varepsilon,$$

for all sufficiently large n' . In other words, \mathbf{A} has to guess at least $\alpha n'$ characters correctly to achieve a competitive ratio of $2 - \alpha - \varepsilon$. Using Corollary 1, we get a lower bound on the number of advice bits necessary to achieve a competitive ratio of c of

$$\begin{aligned} & (1 + (1 - (2 - c)) \log_2(1 - (2 - c)) + (2 - c) \log_2(2 - c)) n' \\ &= (1 + (c - 1) \log_2(c - 1) + (2 - c) \log_2(2 - c)) n' \\ &= (1 + (c - 1) \log_2(c - 1) + (2 - c) \log_2(2 - c)) \frac{n - 2}{2}. \quad \square \end{aligned}$$

Note that, without advice, an online algorithm for MAXCLIQUE can achieve a competitive ratio of $(n' + 2)/((n' + 2)^2/(2n' + 2)) = (2n' + 2)/(n' + 2) \approx 2$ by just taking every vertex.

Acknowledgments

The authors would like to thank Kfir Barhum and Richard Královič for enlightening discussions.
