Abstract

Background: In Pakistan, nearly half of children younger than 5 years are stunted, and 1 in 3 is underweight. Micronutrient deficiencies, a less visible form of undernutrition, are also endemic. They may lead to increased morbidity and mortality as well as to impaired cognitive and physical development.

Objective: To estimate the lifetime costs of micronutrient deficiencies in Pakistani children aged between 6 and 59 months.

Methods: We develop a health economic model of the lifetime health and cost consequences of iodine, iron, vitamin A, and zinc deficiencies. We assess medical costs, production losses in terms of future incomes lost, and disability-adjusted life-years (DALYs). The estimation is based on large population surveys, information on the health consequences of micronutrient deficiencies extracted from randomized trials, and a variety of other sources.

Results: Total societal costs amount to US\$46 million in medical costs, US\$3,222 million in production losses, and 3.4 million DALYs. Costs are dominated by the impaired cognitive development induced by iron-deficiency anemia in 6- to 23-month-old children and the mortality caused by vitamin A deficiency. Costs are substantially higher in poorer households.

Conclusions: Societal costs amounted to 1.44% of gross domestic product and 4.45% of DALYs in Pakistan in 2013. These costs hinder the country's development. They could be eliminated by improved nutrition of 6- to 59-month-old children and public health measures. Our results may contribute to the design of cost-effective interventions aiming to reduce micronutrient deficiencies in early childhood and their lifetime consequences.

Figure 1. Overview of health economic model of societal costs of selected micronutrient deficiencies (MNDs). The social costs of MNDs are calculated in a health economic model proceeding in 4 steps: Step 1 stratifies 6- to 59-month-old Pakistani children in 20 groups (by age-group and socioeconomic status). Step 2 assesses the levels of MNDs in each of these groups. Step 3 assesses the health consequences of the current levels of MNDs. Step 4 assesses the societal costs of these health consequences in 3 cost dimensions.

Introduction

Micronutrient deficiencies (MNDs) are a serious but often invisible form of undernutrition, also called hidden hunger. MNDs increase the morbidity and mortality in children younger than 5 years. They also impair a child's cognitive and physical development and long-term outcomes, thus leading to adverse health outcomes, lower productivity, and lower incomes in adult life.^{1,2} Widespread MNDs will therefore hinder a country's economic development.

MNDs are endemic in children younger than 5 years in Pakistan with 43.8% with iron deficiency anemia (IDA), 54.0% with vitamin A deficiency (VAD), and 39.2% with zinc deficiency (ZnD) in 2011. Among school-age children, 36.7% may be at risk of iodine deficiency (IoD).³ These high levels of deficiencies have been recognized for decades, but except for a substantial improvement in iodine status, very little progress has been made in eradicating them.³

The high costs of nutritional deficiencies and the substantial economic benefits of nutritional interventions have been previously assessed.⁴⁻⁶ However, there is still a need for a deeper understanding of the societal costs of MNDs in the countries affected, as it may increase the awareness of decision makers for their severe and

multiple consequences. It may also contribute to the design of effective and cost-effective nutritional interventions by helping to identify the socioeconomic strata (SES), age-groups, and micronutrients with the highest potential for cost reduction in a specific population.

The aim of this study was to assess the societal costs of MNDs in a birth cohort of Pakistani children affected by MNDs between the age of 6 and 59 months. The micronutrients considered include iodine, iron, vitamin A, and zinc. We assessed medical costs, production losses in terms of future incomes lost, and healthy life-years lost. The study follows an incidence-based lifetime cost approach and thus calculates cost consequences of MNDs in childhood over the whole lifetime of the children affected.

Methods

We developed a health economic simulation model that estimates the lifetime health and cost consequences of IoD, IDA, VAD, and ZnD in 6- to 59-month-old Pakistani children. Infants younger than 6 months were excluded due to lack of data. The model is an extension of a previously published model^{7,8} to Pakistan and additionally integrates the consequences of IoD and xerophthalmia as a consequence of VAD. Figure 1

Table 1. Biomarkers for Micronutrient Status and Threshold Values for Deficiencies.^a

Micronutrient	Monitoring Indicators	Threshold Values for Micronutrient Deficiencies	Source
Iodine	Urinary iodine concentration (UIC)	Mild: UIC = 50-99 µg/L Moderate: UIC = 20-49 µg/L Severe: UIC < 20 µg/L	11
Iron	Serum hemoglobin (Hb)	Mild: Hb < 110 g/L Moderate: Hb < 100 g/L Severe: Hb < 70 g/L	14
Vitamin A	Serum retinol	20 µg/dL	15
Zinc	Serum zinc	60 µg/dL	3

IDA, iron deficiency anemia; VAD, vitamin A deficiency; ZnD, zinc deficiency.

^aThe distribution of the biomarkers for IDA, VAD, and ZnD was calculated based on their means and standard deviations (SD) and by assuming a normal distribution.

and the following sections give an overview of the model and the data used. Appendix 1 illustrates further details of the model.

The model is based on a variety of data sources. They include 2 large population surveys (the 2012-2013 Pakistan Demographic and Health Survey [PDHS]⁹ and the 2011 Pakistan National Nutrition Survey [NNS]³), a survey on the treatment costs in Pakistan of diseases induced by MNDs (see Appendix 2), data from national and international agencies, and data extracted from systematic reviews and other publications.

Model Population

In a *first step*, we stratified the model population of 6- to 59-month-old children by 10 SES and by 2 age-groups (6- to 23-month-old and 24-59-month-old). The model population was obtained from the PDHS 2012-2013, which is based on a representative sample of 14 000 households.⁹ We stratified by age-groups because the 6- to 23-month period is part of the first 1000 days of life, which have been identified as a crucial period to establish a lasting foundation for health.¹⁰ The 10 SES were built upon the distribution of households across the deciles of a wealth index calculated according to the PDHS methodology.⁹ We adjusted all age-groups to the average size of a birth cohort and then extrapolated the sample size to the total population of Pakistan in 2013.

Prevalence of MNDs

In a *second step*, we calculated the prevalence of MNDs in each subgroup based on the Pakistan NNS 2011, which covers a representative sample of 30 000 households.³ The prevalence was determined with micronutrient-specific biomarkers and World Health Organization (WHO) threshold values (Table 1). The prevalence of IoD was assessed with urinary iodine concentration (UIC) from spot urine samples in school-age children. Because there is substantial day-to-day variation in spot UIC, a single UIC should generally not be used to categorize the iodine status of individuals. However, WHO states that the percentage of individuals in a population UIC distribution that are below the UIC thresholds (Table 1) can be considered at risk for low-iodine intakes.¹¹ The prevalence of IDA was based on the altitude-adjusted hemoglobin (Hb) values, and the fraction of anemia attributable to iron deficiency was defined at 60%.^{12,13} The prevalence of VAD and ZnD was based on the serum retinol and serum zinc concentrations, respectively.

Health Consequences

In a *third step*, we modeled the relationship between MNDs and their health consequences. This information was extracted from systematic reviews and primary studies examining the effects on health outcomes of micronutrient supplementation trials with 6- to 59-month-old children. We assumed that the micronutrient

Figure 2. Time dimensions of the health economic model. The health economic model follows an incidence-based approach and assesses the lifetime costs of micronutrient deficiencies (MNDs) in a birth cohort exposed to MNDs from the age of 6 to 59 months. These costs include reversible and permanent effects and are modeled over the whole lifespan of the birth cohort. Future production losses are discounted to present value.

supplements provided in these trials are able to close the gap necessary to meet the micronutrient requirements. The health consequences of the MNDs can therefore be derived from the difference in the health outcomes between the intervention groups and the control groups. This approach has been previously proposed.¹⁶ Mortality was modeled as a population attributable fraction of all-cause mortality.¹⁷

Costs of Health Consequences

In a *fourth step*, we modeled the societal costs of MNDs as the lifetime costs of a birth cohort exposed to MNDs at the age of 6 to 59 months (Figure 2). Some of the health consequences of MNDs are reversible and will occur only in the 6- to 59-month age period, while other consequences are permanent (nonreversible). Medical costs arise as household expenditures for the treatment of the diseases attributed to MNDs and were assessed in a survey conducted by our group in 2015 in the districts of Hyderabad and Faisalabad. The methods and results of the survey are presented in Appendix 2.

Production losses arise due to lower future wages as children affected by impaired cognitive or physical development will be less productive as adults. These losses were measured as future gross income losses based on SES-specific wages. Current wages according to the International Labor Organization¹⁸ were extrapolated to the future by assuming an income growth equal to the yearly average in the previous decade. Future wage differences between SES were calculated

by adjusting the current income distribution⁹ for the social mobility between SES according to a recent study based on the Pakistan Panel Household Survey.¹⁹ Production losses were discounted to present values with a discount rate of 3%²⁰ and converted to US Dollars with the mean exchange rate of 2013.

Life-years lived with disability and lost due to premature mortality were measured in disability-adjusted life-years (DALYs).²¹ Following the recent practice by the Institute of Health Metrics and Evaluation, we did not discount future DALYs.²¹ Note that reporting both production losses and DALYs does not lead to double counting, as a number of health economic studies have shown that measures of production losses and of health-related quality of life do not overlap.²²

Sensitivity Analysis

In order to test the robustness of the results, we ran a probabilistic and univariate sensitivity analysis (SA). Although the univariate SA shows the impact of the most important model parameters, the probabilistic SA creates a range of possible model outcomes. It also determines the confidence intervals of the main model outcomes. The model was implemented in R version 3.1.1.

Ethics Statement

The data sets used in this study were obtained from the PDHS 2012-2013 and the NNS 2011.^{3,9} Ethical review of the analysis was not

	24-59		2.00 (0.038)		

Abbreviations: MNDs, Micronutrient deficiencies; IoD, iodine deficiency; IDA, iron deficiency anemia; UIC, urinary iodine concentration.

^aThe table reports the prevalence of MNDs by type of micronutrient, age-group, and severity (only for IoD and IDA). Due to lack of data regarding the UIC in the 6-59-month-old children, school-age-children are being used as a proxy for the prevalence of IoD. Author’s calculations based on National Nutrition Survey, 2011-2012.

Figure 4. Prevalence of iron-deficiency anemia and vitamin A deficiency by age-group, severity, and SES (%). Households are split into SES deciles of equal size for the whole country. Authors’ calculation based on NNS 2011-2012. SES indicates socioeconomic strata; PDHS, Pakistan Demographic and Health Survey; NNS, Pakistan National Nutrition Survey.

for mild IoD. IDA affected 39% of children and was higher in the 6- to 23-month-old group. Nearly half of the children were affected by VAD and 1 in 3 children by ZnD. Although prevalence of IDA and VAD decreased with increasing wealth, we could not stratify ZnD and IoD by SES due to data limitations.

Health and Cost Consequences

The health and cost consequences of MNDs in 6- to 59-month-old children are summarized

in Figure 5 and Tables 4 and 5. IoD in this age-group of children may lead to mental impairment.¹¹ Mild to severe IoD may cause functional and/or structural changes in the brain leading to reversible and to permanent (nonreversible) loss of IQ points.²³ As there are no data quantifying the ratio of reversible to permanent damage of IoD on brain development, for the purposes of this analysis, we assume that the permanent effect is equal to one-third of the total effect on mental impairment and occurs only in 6- to 23-month-old

Figure 5. Health and cost consequences micronutrient deficiencies. Numbers refer to the model parameters which are described in Tables 4 and 5 (first number refers to the table. Second number refers to the line in the table). Dotted lines represent long-term consequences.

children. We also assume that permanent loss of IQ points leads to future production losses and DALYs, whereas reversible loss of IQ points leads only to current DALYs (see Appendix 1).

The health consequences of IDA vary by severity and age-group. IDA may lead to impaired cognitive development, low physical activity, and increased all-cause mortality (severe IDA only). Moderate and severe IDA may cause permanent cognitive impairment in 6- to 23-month-old children affecting their productivity in adulthood. Although several studies have found a substantial effect of iron deficiency on cognitive ability,³³⁻³⁵ only Lozoff et al³³ have assessed the long-term effect on IQ and estimated it separately for children in mid-income and low-income households. Our model is based on the lower effect estimated in the mid-income group,

as the higher effect in the low-income group might be biased due to adverse circumstances not purely attributable to IDA. IDA also reduces physical activity leading to reversible DALYs. Premature mortality due to severe IDA leads to future production losses and DALYs.

The health consequences of VAD include xerophthalmia and increased risk of diarrhea, measles, and all-cause mortality.²⁹ Bitot spot and night blindness are the first and most pervasive symptoms of xerophthalmia in young children.³⁶ They lead to current DALYs but are fully reversible with vitamin A supplements. Diarrhea and measles lead to direct medical costs and DALYs. Premature all-cause mortality leads to future production losses and DALYs.

The health consequences of ZnD include stunting and diarrhea.³⁰ Stunting has a long-

Table 4. Health Consequences of Micronutrient Deficiencies.^a

Micronutrient Deficiency	Health Consequence	Effect Size (RR; 95% CI)	Persistent Effect	Number in Figure 5	Source
Iodine deficiency (IoD)	Cognitive impairment: Mild IoD → borderline and mild cognitive impairment	Mild IoD: loss of 2.25 IQ points in school-age-children	Partially	4.1	Authors' calculations based on ²⁴ SR
	Moderate and Severe IoD → borderline, mild and moderate cognitive impairment	Moderate IoD: loss of 5.25 IQ points in school-age-children			
		Severe IoD: loss of 20.25 IQ points in school-age-children and adults			
Iron deficiency anemia (IDA)	Share of anemia caused by iron deficiency	60%		4.2	¹² SR; ¹³
	6-23 month-old only: Moderate IDA → borderline cognitive impairment	Moderate and severe IDA: IQ in adults reduced by 9 IQ points	Yes	4.3	²⁵⁻²⁷ GBD
	Severe IDA → mild cognitive impairment				
	Low physical activity	Mild to severe IDA: all children affected	No	4.4	²⁶

^aEffect sizes were extracted from the literature (see last column). Health consequences are assumed to be equal for both age-groups, with the exception of the permanent cognitive impairment due to IoD and the cognitive impairment due to IDA.

term negative effect on adult wages. The cost consequences of diarrhea were calculated as for VAD. Table 6 presents additional economic parameters used in the health economic model.

Societal Costs of MNDs

Combining the information on the prevalence of MNDs with the information on the health and cost consequences of these deficiencies, we estimated the total lifetime costs of MNDs in 6- to 59-month-old children in Pakistan in 2013 (Table 7). The costs accounted for US\$46 (95%

confidence interval [CI] 26.1-71.5) million in medical costs, US\$3,222 (95% CI 1135-7725) million in production losses, and 3.4 (95% CI 2.5-4.4) million DALYs. They represent the lifetime costs of a birth cohort affected by IoD, IDA, VAD, and ZnD between the age of 6 and 59 months and may also be interpreted as the costs that could be prevented every year by completely eliminating these MNDs in this age-group.

Costs were dominated by MNDs in 6- to 23-month-old children, with 92.6% of production losses and 79.9% of DALYs (Figure 6). The high production losses in the 6- to 23-month-old

Table 5. Cost Consequences of Adverse Health Effects.

Health Consequence	Cost Category	Type and Size of Effect	Number in Figure 5	Source
Cognitive impairment	Production losses (future)	1 SD reduction of the cognitive score leads to a reduction of adult wage by 8%	5.1	³¹
	DALYs	Borderline intellectual functioning: DW 0.011 Mild intellectual disability: DW 0.043 Moderate intellectual disability: DW 0.1	5.2	²⁷ GBD

Abbreviations: IDA, iron deficiency anemia; MND, micronutrient deficiency.^aCurrent costs occur at 6 to 59 months of age, while future costs occur after the age of 5. The blank spots in the table show that the MNDs do not produce any costs in these categories and not that these costs have not been considered.

Figure 6. Production losses and DALYs by micronutrient deficiency and cost category (share of respective total). Shares of the production losses (A) and DALYs (B) by age-group (6- to 23-month-old and 24-59-month-old), type of micronutrient deficiency and type of cost (current, future life, and mortality). Areas in black represent minor cost categories. IDA, iron deficiency anemia; loD, iodine deficiency; VAD, vitamin A deficiency; ZnD, zinc deficiency; mort, mortality; fut, future; DALYs, disability adjusted life years.

Figure 7. Production losses and DALYs due to iron deficiency anemia and vitamin A deficiency by socioeconomic strata. Households are split into deciles of equal size for the whole country. The societal costs of zinc deficiency and iodine deficiency are not represented as their prevalence could not be calculated by socioeconomic strata. IDA, iron deficiency anemia; VAD, vitamin A deficiency; DALYs, disability adjusted life years.

children were due to the impaired cognitive development induced by IDA and IoD. The IDA was responsible for over two-thirds of all production losses and over half of all DALYs. The VAD and IoD were respectively the second and third most important causes for both production losses and for DALYs. ZnD played only a minor role for production losses and was negligible for DALYs.

The comparison between the societal costs of MNDs in children living in the poorer and wealthier households is presented in Figure 7. Costs were higher in poorer households due to the higher prevalence and severity of deficiencies and the higher number of children. Differences were particularly strong for VAD with 4 times higher production losses and 6 times higher DALYs in the poorest than in the wealthiest third of households.

Results of SA

The tornado diagrams show the effect of a 10% increase or decrease in the model parameters (Figure 8). Production losses were most influenced by the discount rate, the work-related parameters (work force participation rate, wage, income growth), parameters relating to the effect of IDA on cognition, and by the relative risk of mortality with VAD. DALYs were most influenced by the relative risk of mortality with VAD and the parameters related to the impact of IDA

(share of anemia attributable to IDA, disability weights of intellectual disability, and relative risk of mortality with IDA).

For the probabilistic SA, we randomly varied all model parameters within predefined distributions and then ran the model 10 000 times. Where information on the variability of the parameters was not available from the literature, we chose an SD equaling 20% of the mean. Figure 9 shows the distribution of total production losses and total DALYs together with 95% CIs according to the multivariate SA. The CIs around our estimates are relatively narrow with 95% of all model runs demonstrating production losses between US\$1.1 and US\$7.6 billion and 95% of DALYs between 2.5 and 4.4 million DALYs.

Discussion

We assessed the societal costs of MNDs in 6- to 59-month-old Pakistani children in 2013. The costs were calculated as the lifetime cost consequences of the current levels of iodine, iron, vitamin A, and zinc deficiencies in a yearly birth cohort. Total societal costs amounted to medical costs of US\$46 million for the treatment of illness attributable to MNDs, to production losses of US\$3,222 million due to future incomes lost, and to 3.4 million DALYs due to premature deaths and years lived with disability. These costs

Figure 8. Univariate sensitivity analysis of production losses and DALYs. Dark blue bars show the effect of a 10% increase in a parameter, while light blue bars show the effect of a 10% decrease in a parameter. RR, relative risk; DW, disability weight; IoD, iodine deficiency; IDA, iron deficiency anemia; VAD, vitamin A deficiency; ZnD, zinc deficiency; DALYs, disability adjusted life years.

Figure 9. Multivariate sensitivity analysis by type of societal cost. Distribution of total production losses and total DALYs in 10 000 model runs. The dotted lines represent 95% confidence intervals. DALYs indicate disability adjusted life years.

represent a substantial burden for Pakistan and correspond to 1.44% of GDP in 2013 lost due to lower future productivity and to 4.45% of the overall burden of 77.3 million DALYs in 2013.²¹ These costs can be interpreted as the costs that could be prevented every single year if MNDs could be completely eliminated in 6- to 59-month-old children.

Costs occurring at the age of 6 to 23 months were substantially higher than those at the age of 24 to 59 months because of the higher prevalence of MNDs and the more severe health consequences at younger age. The same reasons led to higher costs in poorer households. However, costs were substantial even in the wealthiest household decile. IDA had the most severe cost consequences accounting for two-thirds of total costs. The costs of VAD and IoD were also substantial, while the costs of ZnD were limited.

Production losses were dominated by future income losses due to impaired cognitive and physical development. They affect the country's economic growth and contribute to an undernutrition-based poverty trap in which children born in poor households are more likely to become poor parents themselves.

Our study is based on a health economic model simulating the lifetime consequences of MNDs in young children by combining information from clinical and epidemiological studies with economic data.⁴⁴ The model incorporates the currently available evidence on the prevalence of MNDs in Pakistan, on their health consequences in young children, and on their long-term effects. The model might be criticized for the long causal chains linking MNDs in early childhood to health and cost outcomes over the whole lifespan. However, there is no alternative to this approach, as randomized controlled studies tracking outcomes over such a long time period are not available.

A previous study has estimated the lifetime consequences of IDA in Pakistani children on production losses at 0.75% of GDP in 1996.⁴⁵ This result is of the same magnitude as ours, although it based on older literature on the impact of IDA on cognition and not limited to 6- to 59-month-old children.

Our model differs from other epidemiological models describing the consequences of MNDs

such as the Life Saved Tool⁴⁶ or the PROFILES model,⁴⁷ as it considers morbidity as well as mortality and assesses the cost consequences in the 3 dimensions (medical costs, production losses, and DALYs). Furthermore, it differentiates by the socioeconomic status of households and between 6- to 23-month-old and 24- to 59-month-old children. We believe that this model is particularly well suited to capture the multiple often irreversible health and cost consequences of MNDs in these children.

Several limitations of our analysis should be recognized. *First*, the methods used to assess the prevalence of IoD are a major source of uncertainty. The prevalence of IoD was measured with the proxy of a spot UIC in school-age children due to lack of data on 6- to 59-month-old children. The high day-to-day, within-person variance in UIC may lead to an overestimation of the prevalence of IoD and of its cost consequences. However, the magnitude of this overestimation is not clear, as it depends on the iodine intake from children's diet. *Second*, we could not consider all the MNDs which may affect 6- to 59-month-old children but only those that were assessed in the 2011 NNS. The survey did, for example, not assess the folate and vitamin B 12 status of children. The presence of relevant deficiencies of these micronutrients would lead an underestimation of the costs of MNDs. *Third*, we could only consider those health consequences that had been investigated and were identified in the micronutrient supplementation trials. Particularly, the long-term health consequences are rarely assessed in these trials, which may lead to an underestimation of the costs of MNDs. *Fourth*, a possible overlap of the effect of single MNDs on the same health outcome could not be determined as in the case of the effect of IDA and IoD on cognitive development. This lack of control for a possible overlap may lead to an overestimation of costs.

The high levels of MNDs in Pakistan have been recognized for decades, but with the exception of IoD, very little progress has been made in eradicating them.³ Although economic growth may contribute to improve the nutritional content of diets, it is not sufficient to solve the problem as illustrated by the considerable levels of MNDs in

children living in relatively wealthy Pakistani households. The micronutrient status of the population must thus be improved by increasing micronutrient intake through food fortification and supplementation.

The Pakistan Standards and Quality Control Act has issued specifications for the mass fortification of staple foods such as wheat flour, edible oil and ghee, and iodized salt.⁴⁸ So far, only iodized salt has been successful by reaching a household coverage of 69% in 2011.³ Efforts for the mass fortification of other staple foods, such as the fortification of edible oil with vitamin A or of wheat flour with iron and folate, have been largely unsuccessful due to weak legislative support and a poor regulatory environment.⁴⁸ The provision of micronutrient supplements to populations with particularly high nutritional needs is another strategy for reducing MNDs.⁴⁹ Vitamin A supplementation has reached a high coverage in 6- to 59-month-old children in Pakistan with 72%.⁹ However, the persistently high levels of VAD among these children show that supplementation, although effective in controlled trials, may not be sufficient.

Our results confirm the urgent need for policies aiming at an improvement in the micronutrient status of 6- to 59-month-old children. Interventions should in particular target 6- to 23-month-old children, as social costs of MNDs are dominated by the costs occurring in this age-group. Such policies may include the promotion of dietary diversity and complementary feeding, food fortification as well as multiple micronutrient supplementation.⁴⁹ Furthermore, interventions aiming to eradicate MNDs in young children should not only be aimed at children but also at their mothers, as the low body stores of micronutrients in young children may also be the consequence of maternal undernutrition in pregnancy and while breastfeeding.

In conclusion, our study reveals the severe cost consequences of iodine, iron, vitamin A, and zinc deficiencies in young Pakistani children. Most of these costs are invisible to the parents, as they will occur over the future lifetime of the child. As our results identify the areas of highest societal costs of MNDs, they may be useful for the design and the implementation of interventions

aiming to maximize the effect of the available financial resources. Future research should focus on further improving the knowledge on the living conditions and on the inadequate nutrition responsible for MNDs. This research could be strengthened with refined population surveys collecting richer data on health, nutrition, exposition to policy measures, and socioeconomic conditions.

Declaration of Conflicting Interests

The author(s) declared no potential conflicts of interest with respect to the research, authorship, and/or publication of this article.

Funding

The author(s) disclosed receipt of the following financial support for the research, authorship, and/or publication of this article: This work was funded through an unrestricted grant from Nestlé Research Center. Additional direct and in-kind support was received from the Aga Khan University, the ETH Zurich, and the Zurich University of Applied Sciences.
