Recent findings suggest that pain and pleasure share common neurochemical circuits, and studies in animals and humans show that opioid-mediated descending pathways can inhibit or facilitate pain. We explored the role of endogenous opioid neurotransmission in pleasure-related analgesia. μ-opioidergic activity was blocked with 0.2 mg/kg naloxone to assess its effects on hedonic responses to pleasant emotional pictures (International Affective Picture System) and its modulating effects on heat pain tolerance. Naloxone did not alter subjective and autonomous reactions to pleasure induction or overall mood of participants. In addition, pleasure-related increases in pain tolerance persisted after reversal of endogenous μ-opioidergic neurotransmission. Subjective pain intensity and unpleasantness ratings increased after naloxone administration. These findings suggest that, in addition to opioid-sensitive circuits, mainly opioid-insensitive pain-modulating circuits are activated during pleasure-related analgesia.
ant emotional pictures [International Affective Picture System (IAPS)] and reduce pleasure-related analgesia. In particular, we analyzed the effects of naloxone during pleasure induction on heat pain tolerance, subjective pain intensity and unpleasantness, self-reports on valence and arousal of experienced affective states, autonomic reactions (startle magnitude and skin conductance level) and overall mood.

Materials and Methods

Participants. Twenty-two healthy right-handed male volunteers (mean age, 26.5 years; range, 19–44) were included in the study. All participants had normal pain thresholds at the site of stimulus application (Yarnitsky et al., 1995; Schaffner et al., 2008), no history of neurological or psychiatric disease or drug abuse, no history of chronic or acute pain, and were not taking any form of analgesic, antidepressant, anti-anxiety or anti-stress medication. Participants were asked to refrain from alcoholic beverages 12 h before the experiment. Handedness was determined using a standard handedness inventory (Chapman and Chapman, 1987). The study was conducted in accordance with the Declaration of Helsinki on the treatment of human subjects and was approved by the local research ethics committee and federal authorities. All participants gave written informed consent before participating in the study and were free to withdraw from the study at any time. They were instructed about the double-blind administration of naloxone and informed that no side effects were expected at the doses used. In addition, participants were told that the administered substance could increase, decrease, or not alter pain perception.

Drug administration. Participants were randomly assigned in a double-blind manner to either a naloxone or a control group. An intravenous catheter was placed in the antecubital vein of the nondominant arm at the beginning of the experimental session. In between blocks, participants in the naloxone group were administered naloxone hydrochloride (0.2 mg/kg; concentration 1 mg/ml) and subjects in the control group an equivalent volume of saline (0.9% NaCl). Similar naloxone dosages have been previously shown to completely antagonize endogenous opioid-mediated analgesia in healthy volunteers (Amazno and Benedetti, 1999).

Emotional stimuli. We used a standardized selection of highly pleasant emotional stimuli from the IAPS (Lang et al., 2004). These pictures have been shown to robustly induce positive affective states and pleasure-related analgesia (de Wied and Verbaten, 2001; Meagher et al., 2001). For each block, a set of 15 pictures was selected (picture sets 1 and 2). Care was given to ensure that both sets of pictures were equivalent in mean normative valence and arousal ratings for male subjects (picture set 1: valence mean, 7.58; SD, 1.43; arousal mean, 6.56; SD, 2.01; picture set 2: valence mean, 7.38; SD, 1.39; arousal mean, 6.28; SD, 2.00). Stimuli consisted mainly of erotic (couples in erotic poses, nude females) and sports pictures. According to the motivational priming hypothesis by Lang and coworkers (1990), erotic pictures, having great motivational relevance, lead to strong appetitive system activation and arousal (Bradley et al., 2006). IAPS slide numbers for the two picture sets used were as follows: picture set 1: erotic: 4220, 4225, 4461, 4651, 4659, 4670, 4680; sports: 5621, 5626, 8080, 8186, 8199, 8297, 8071; picture set 2: erotic: 4250, 4599, 4611, 4652, 4653, 4658, 4660, 4695; sports: 8170, 8185, 8200, 8370, 8496, 2303, 7330. To control for position effects, the two parallel versions of the questions were used for both the set of erotic pictures and the set of sports pictures. The two versions were presented on two consecutive visual analog scales (VASs) with the endpoints “no pain” and “worst pain experienced,” and “neutral” and “extremely unpleasant,” respectively. The VASs were presented on a monitor screen. Participants gave their ratings by mouse clicking the pursuant position on the VAS. The obtained ratings were then transformed into scores between 0 and 10. To assess whether the induction of a positive affective state was effective, and to estimate whether naloxone altered hedonic responses to pleasant emotional stimuli, participants gave ratings regarding valence and arousal of the affective state they experienced on a computerized SAM (self-assessment manikin questionnaire). The formulated questions were, for valence: “How pleasant or unpleasant were your feelings while watching the pictures?” and, for arousal, “How arousing were your feelings while watching the pictures?” The SAM consisted of two sets of five pictographs depicting different levels of affective valence and arousal (Lang, 1980). Subjects were asked to click with the cursor on or between the figures. For each dimension, ratings between 0 and 10 were recorded; nonresponses were scored as zero magnitude blinks (13 of 132 blinks).

Pain stimuli. Noxious heat stimulus were administered using a 30 × 30 mm Peltier device (TSA-II; Medoc) placed on the volar aspect of the nondominant forearm. Pain threshold was measured at the beginning of the experiment: volunteers were asked to stop the heat stimulus when they felt it turning from “hot” to “painful.” For individual pain tolerances, participants were asked to stop the increasingly painful stimulus at the point they could not stand it any longer. Pain threshold and pain tolerances were determined by calculating the average of three measurements starting at 35°C with a constant rise of temperature (0.8°C/s). To avoid physical injuries, the heating device was preprogrammed so that it stopped automatically at a maximum temperature of 52°C. To diminish visual distraction, participants were asked to close their eyes during the full length of pain measurements. For pain tolerance measurements right after picture presentation, we asked participants “to ask in the affective state they experienced while looking at the pictures.”

Autonomic reactivity. Skin conductance level (SCL) and startle blink electromyographic (EMG) response were measured with an eight-channel Varjoport measurement system (Becker Meditec) and were saved on a compact flash card for off-line analyses. Sampling rate was set to 256 Hz for SCL and to 1024 Hz for EMG recordings. Skin conductance electrodes (Ag/AgCl, 5 mm contact area diameter; Marquette Hellige Medical Systems) filled with lubricating jelly (SCL-Paste, 0.5% NaCl; Becker Meditec) were placed adja-
cently on the hypothenar eminence of the palm of the nondominant hand, which was cleansed in advance with distilled water. SCL raw data of each participant was amplified, dedrifted, rectified, and averaged throughout the picture-viewing periods in each block (180 s). Startle blink responses were recorded from the orbicularis oculi muscle beneath the left eye, using two 4 mm Ag/AgCl electrodes placed 1.5 cm apart and a ground electrode placed on the mastoid bone following guidelines by Blumen-thal et al. (2005). Startle responses were elicited by a 50 ms, 90 dB(A) burst of white noise with instantaneous rise time presented binaurally over Philips SBCHP195 headphones. For each block, blink magnitudes of three startle probes presented during picture viewing were averaged; nonresponses were scored as zero magnitude blinks (1.3 of 132 blinks). Startle probes were presented 3000 ms after picture onset.

Subjective ratings. Subjects rated their pain intensity and unpleasantness on two consecutive visual analog scales (VASs) with the endpoints “very well” and “very bad” and “well” and “very well,” respectively. The VASs were presented on a monitor screen.

Experiment procedure. At the beginning of each experimental session, participants were screened for medical problems (self-report) and were told that the main aim of the study was evaluating the impact of emotional pictures on the individual affective state. To prevent participants from focusing on the painful stimulus and to focus their attention on pleasure induction, the occurrence of noxious heat stimuli was men-
dioned but not as a principal study goal. After determining the weight of
volunteers and the insertion of an intravenous catheter, participants were seated in front of a monitor in a dimly lit room. The experimenter affixed the thermode and the electrodes for autonomic reaction measurements and asked participants to follow the instructions presented on the computer screen (SuperLab 4.0). The experiment was divided into two blocks (Fig. 1). In each block, one of the two picture sets was presented. Right before and after picture presentation, pain tolerance succeeded by subjective pain ratings (VAS) was assessed. At the end of each block, participants rated the affective state they had experienced while watching the pictures (SAM). Right before block 1, and immediately after block 2, mood ratings were assessed (MDBF). In between blocks, naloxone or saline was administered. Special care was given so that participants did not feel any pain or worry about the procedure. While waiting for the onset of naloxone effects after intravenous administration (~2 min) and to distract subjects from the just experienced drug administration, a short (3 min) geometrical task was displayed on the monitor (meaningless geometric figure pairs had to be judged for similarity).

The experiments were performed according to a randomized double-blind design. For safety reasons (potential unforeseen side-effects of naloxone), the experimenter and the medical doctor stayed behind a partition in the same room. To control for confounding factors associated with circadian variations and the experimenter’s presence, all participants were tested in the afternoon and by the same experimenter. At the end of an experimental session (total duration, ~70 min), volunteers were debriefed about the experimental aims and received a monetary compensation for their participation in the study.

Data analysis. For pain tolerance measurements, pain, and emotional ratings, repeated-measures ANOVAs were performed. Within-subject factors were block (block 1: before injection vs block 2: after injection) and time (before picture viewing vs after picture viewing), with group (naloxone vs control) as a between-subject factor. p values in the ANOVAs and t tests were corrected using Greenhouse–Geisser and Bonferroni correction, respectively. Post hoc comparisons were performed using two-tailed Student’s paired t tests. Correlations between skin conductance levels were calculated separately for both groups using Pearson’s correlation coefficient. In the analysis of subjective pain ratings, Grubb’s test for outliers uncovered one outlier, which was therefore excluded from VAS analyses. Significance level was set at p < 0.05 for all statistical calculations.

Results
Expectation
Seventy-seven percent of the study participants believed they had received saline. Two participants who thought they had received naloxone were in the naloxone group and the other three were in the control group.

Pain tolerance
The repeated-measures ANOVA with the factors group, block, and time was significant for the factor time; after picture viewing tolerances were higher (F(1,20) = 29.61, p = 0.000). The factor block was also significant; tolerances were lower in block 2 (F(1,20) = 16.82, p = 0.001). The block-by-time interaction was significant as well (F(1,20) = 18.54, p = 0.000) (Fig. 2). Post hoc t tests confirmed that pain tolerance increased significantly after picture viewing for both blocks (block 1: t(21) = −2.94, p = 0.008; block 2: t(21) = −5.67, p = 0.000), but decreased after injection [(block 1 pre-picture viewing) − (block 2 pre-picture viewing); t(21) = 4.70, p = 0.000]. No other effects were significant, suggesting that naloxone influenced neither pain tolerance nor pleasure-related analgesia.

Pain ratings
For pain intensity, a significant effect found for the factor block was that pain intensity ratings were higher after injection (F(1,19) = 5.35, p = 0.032). Both scales showed a significant block-by-group interaction (intensity: F(1,19) = 4.52, p = 0.047; unpleasantness: F(1,19) = 4.31, p = 0.050). Post hoc t tests uncovered that the naloxone group gave higher pain ratings after injection (intensity: t(9) = −3.48, p = 0.006; unpleasantness: t(9) = −2.57, p = 0.028), whereas control group ratings did not change significantly (intensity: t(9) = −0.120, p = 0.91; unpleasantness: t(9) = 0.122, p = 0.91) (Fig. 3). No other effects were seen.

Picture ratings
Data for blocks 1 and 2 confirm that the picture sets induced the targeted pleasant affective state (mean valence, >7.5; mean arousal, >5.5). For SAM valence, we found a significant effect for
the experiment, uninfluenced by naloxone. The valence ratings for the affective state decreased in block 2, yet still mirrored highly pleasant states (mean, >6.8). We found no block-by-group interaction for either scale, suggesting that naloxone did not alter hedonic responses to pleasant visual stimuli. Affective state ratings for block 1 did not differ depending on picture set 1, indicating that the emotional impact of both picture sets was equivalent (independent samples t test for valence and arousal, p > 0.27).

**Autonomic reactivity**

Averaged SCLs throughout the picture viewing periods were not significant for the factor block, nor the block-by-group interaction (both p > 0.46). Conversely, correlation analyses between skin conductance levels in block 1 and block 2 were significant in both groups (control: r = 0.471, p < 0.001; naloxone: r = 0.484, p < 0.001), confirming that hedonic response, in terms of SCL, was not affected by naloxone. Analogously, averaged startle magnitudes during pleasure induction were not significantly altered by blockade of endorphinergic activity (block and block-by-group, p > 0.13).

**Mood**

The factor scale was significant (F(1,20) = 3.52, p = 0.050), whereby post hoc t test of scale ratings did not survive Bonferroni corrections, suggesting that ratings for “feeling well versus not well,” “feeling alert versus tired,” and “feeling calm versus aroused” did not differ. Moreover, the block-by-time and block-by-group interactions were not significant (both p > 0.19), indicating that mood was constant during the experiment, uninfluenced by naloxone.

**Discussion**

Our study examined the contribution of endogenous opioids in emotional pain modulation. We hypothesized that enhanced opioidergic neurotransmission during positive affective states contributes to pleasure-related analgesia. Contrary to our expectations, hedonic response to pleasant visual stimuli and altered pain tolerances were insensitive to naloxone. Subjective pain intensity and unpleasantness ratings increased after naloxone injection.

Positive affective states are associated with enhanced opioidergic activity (Boecker et al., 2008; Koepp et al., 2009) and negative states with its deactivation (Zubieta et al., 2003). Also, the hedonic responses to external emotional stimuli, such as sweet taste (Berridge, 2003), IAPS pictures (Gospic et al., 2008), and monetary reward (Petrovic et al., 2008), were shown to be modulated by opioids. In our study, mood and subjective ratings of experienced affective states during pleasant-picture viewing were not significantly influenced by naloxone. Corroboratively, skin conductance responses, consistently shown to co-vary with arousal judgments (Lang et al., 1990), and the magnitudes of acoustically elicited startle eye blinks, a reliable marker for the valence of an affective state (Lang et al., 1990), remained unchanged. Current hypotheses suggest that analgesia induced by viewing emotionally loaded pictures grounds on effects from changes in affective state and covariate, hardly dissociable attentional processes (Villemure and Bushnell, 2002). Since subjective and autonomic reactions to pleasure induction and overall mood neither differed between groups nor changed during the experiment, we suggest that the degree of attention was equivalent among participants.

Many studies have identified a major role of the endogenous opioid system in pain modulation by reversing its effects with naloxone (Gracely et al., 1983; Amanzio and Benedetti, 1999; Eippert et al., 2008) and using molecular imaging techniques (Zubieta et al., 2005; Scott et al., 2008). Our findings show that pleasure-related analgesia, measured as an increase in pain tolerance, was insensitive to naloxone injection. After substance administration, we found a substance-unspecific decrease in pain tolerance. It is probable and even likely that the procedure of drug administration (pressure in the vein) was responsible for these results. In line with previous findings on the effects of naloxone on heat-pain measurements, the increased level of subjective pain ratings of intensity and unpleasantness was substance specific (Borras et al., 2004). This result is highly appealing, as it suggests that μ-opioidergic neurotransmission is involved in the subjective response to heat pain. Because pain tolerances after pleasure induction were not attenuated by naloxone, it can be assumed that a major involvement of opioid-insensitive inhibitory systems is at work here. Studies on stress-induced analgesia and on placebo analgesia have similarly proposed the existence of opioid-sensitive and opioid-insensitive descending modulatory systems (Amanzio and Benedetti, 1999; Flor et al., 2002; Ford and Finn, 2008). Several neurotransmitter systems, including dopaminergic, serotonergic, cannabinergic, and monoaminergic, have been shown to play a role in endogenous pain inhibition, but there is still a need for research on these systems (Millan, 2002). Although highly speculative, we consider dopamine signaling as a potential candidate able to preserve hedonic processing in the absence of opioid mediation. Along this line of reasoning, a recent review of the literature has shown a key role of dopamine on pain perception in humans, suggesting its involvement in endogenous pain modulation systems (Potvin et al., 2009). In addition, pleasure and reward expectation have been associated with increased phasic dopamine signaling (Schultz, 2010). Even if the precise role of dopamine in pain and reward is far from unequivocal (Leknes and Tracey, 2008), and its function varies at different time courses (Schultz, 2007), some recent evidence suggests a possible opioid-independent dopaminergic me-
diation of hedonic processes (Scott et al., 2008). It is important to also consider the potential role of endocannabinoids for the present results, as they have been related to nondrug rewarding behaviors (Fattore et al., 2010) and in analgesia (Guindon and Hohmann, 2009). Notably, substantial and complex interactions between endocannabinoid systems and opioids in nociception (Welch, 2009) and dopamine in the processing of motivationally salient information have been described (Laviolette and Grace, 2006). But the interactions are complex and future studies will be needed to further elucidate a separate or cojoint action of these systems in the processing of reward-related analgesia. From a homeostatic perspective, the fact that reversal of endogenous \( \mu \)-opioid neurotransmission did not significantly alter—at least at the behavioral level—hedonic processing and pain inhibition is comprehensible. The notion that both of them are maintained by different complementing, interacting, and overlapping neural and chemical modulatory circuits, quickly equilibrating external disturbances, seems quite compelling if affective processes are conceptualized as action dispositions able to regulate and optimize an individual’s response to motivationally relevant stimuli (Lang et al., 1990).

Three methodological caveats limit the interpretation of our results. First, we measured effects of naloxone on hedonic and pain responses 3 min after bolus administration. We decided to use a short measurement window, compared with other studies, since naloxone is well known for its rapid onset of action, rate of elimination, and distribution being administered in clinical settings in 2–3 min intervals (Ngai et al., 1976; Goldfrank et al., 1986). Although this methodological limitation does not allow for verification of complete receptor blockage by the time of measurement, the significant effects of naloxone on subjective pain ratings support at least a partial blockage of endogenous pain-modulatory mechanisms. Bearing this in mind, it should be expected that having a peak blockage of opioid receptors by using a longer time window would result in even stronger effects. Second, we observed a decrease of subjective valence ratings in block 2 that was group independent and most probably due to habituation effects. This might have resulted in a floor effect preventing naloxone from producing any further changes in valence and arousal. One could argue that viewing pleasant photographs, mostly erotic in nature, within an experimental setting might not have changed the basal level of endogenous opioids, leaving blockage of \( \mu \)-opioid receptors without any consequences. However, this would imply a negligible role of \( \mu \)-opioidergic neurotransmission in hedonic processing since participants clearly experienced positive affective states. Alternative interpretations are possible. It might be that with our experimental design, changes in opioid neurotransmission in core processes of positive affective reaction might have happened, but at levels far too low to be detectable at behavioral levels. Future studies using stronger pleasure-inducing methods, and thus presumably involving pronounced endogenous opioid release, might reveal larger antagonizing effects. The inclusion of neutral affective stimuli in these experimental designs will likely improve the explanatory power of the reported findings. Third, we measured a small sample size, which advises for a cautious interpretation of our results. However, we firmly believe that this study provides preliminary yet clear evidence for opioid-sensitive and opioid-insensitive components of affective regulation and modulation of pain experiences. Future studies using more sensitive measurement techniques focusing on molecular endogenous opioid peptides may also contribute to deepen our understanding of the effects of opioid-insensitive components of affective regulation. Undoubtedly, the further understanding of the neurobiological underpinnings of pleasure-related analgesia will be of great benefit for the clinical management of pain.
