# Acknowledgements

First of all, I would like to thank Prof. Dr. Renato Zenobi for giving me the opportunity to do my PhD in his group. I appreciated his guidance and support over the years. He encouraged me to work independently and supported my decisions at all times, both of which were very helpful to me.

I am grateful to Prof. Dr. Markus Stoffel for agreeing to be my co-examiner and, more importantly, for his ongoing support of my collaborative projects with Dr. Wenjie Ge. I would like to thank my collaborator Dr. Wenjie Ge at ETH Zurich, it was a great pleasure to collaborate with him.

I appreciate Brigitte Bräm and Pamela Knupp for handling all the financial and administrative work. Big thanks go to Marco Zesiger, Christian Marro and Christoph Bärtschi from the mechanical workshop and Heinz Benz from the electronics for all the assistance they provided.

Many thanks to all the current and former group members of the Zenobi lab. I really enjoyed the happy and cohesive atmosphere of the group and the various fun group activities, including the cheese and wine parties, group hikes, group ski outings and Christmas dinners. Many thanks to the plasma team members (Alina and Sandra), as we always say “our team is small but very powerful”, I am very happy that I had a chance to work with you. I also want to thank the other group members that I had a nice time with during my PhD: Bettina, Jiayi, Irina, Masha, Na, Liqing, Nora, Siiri, Despoina, Zhenfeng, Jérôme, Ri, Prince, Jonas, Naresh, Stamatios, Julian, Dusan, Giovanni Luca, Lukas, Philipp, Yash, Adam, Cedric and so on. Thank you all very much for keeping a very nice working environment.

Special thanks to Zhenfeng for his support, encouragement, concern and company, I really cherish and enjoy the time we have spent together and hope we can always be there for each other in the future. Many thanks to my friends at ETH and UZH: Kunkun, Wenjie, Yong, Tongtong and Xingzao, thank you all for giving me so many wonderful memories.

Last but not least, my family in China has my sincere gratitude! My parents have always given me the most love and support. Thank you!

# Abstract

Cellular heterogeneity is essential for physiological functions of organisms, and precise interpretation of the relevant biological mechanisms requires accurate measurement of biomolecules including DNA, RNA, proteins and metabolites at the single-cell level. Cellular metabolites react most rapidly to environmental and biochemical changes, such that the detection of cellular metabolites is a critical step in determining the physiological state of cells. However, their low amounts and structural diversity in single cells and the large variation in the content of different metabolites make single-cell metabolomics analysis technically challenging.

Mass spectrometry, with its high sensitivity, good selectivity, and wide dynamic range, has been widely used in single-cell analysis in recent years. The advancement of single-cell mass spectrometry is inextricably linked to the development of ionization sources, and different ionization methods have their own characteristics and can complement each other.

In this dissertation, home-built ambient ionization sources such as a dielectric barrier discharge ionization (DBDI), a hybrid ionization source combining nanoelectrospray (nanoESI) and DBDI, and a 3D-printed ionization source were used to investigate single-cell metabolomics.

In Chapter 1, some general information about single-cell mass spectrometry is introduced.

In Chapter 2, the basic principles of the methods and instruments used in this thesis are explained.

In Chapter 3, a label-free, rapid single-cell analytical method based on DBDI mass spectrometry, which can detect multiple metabolites in single cells with a throughput of 38 cells/ minute is presented. Several cell types (HEK-293T, PANC-1, CFPAC-1, H6c7, HeLa, and iBAs) were successfully differentiated. In pancreatic

cancer cells, we discovered evidence for abnormal lipid metabolism. We also checked gene expression in a cancer genome atlas dataset and found that the mRNA level of an important enzyme of lipid synthesis (ATP citrate lyase, ACLY) was upregulated in human pancreatic ductal adenocarcinoma (PDAC). Furthermore, both an ACLY chemical inhibitor and a siRNA method targeting ACLY have been shown to reduce the viability of PDAC cells. This study demonstrated that ACLY could be a potential target for treating pancreatic cancer due to a considerable reduction in lipid content in treated cells.

In Chapter 4, a nanoESI-DBDI hybrid ionization source is proposed for single-cell analysis. A capillary with a 1  $\mu\text{m}$  i.d. tip was inserted into cells for sampling and then directly used as the nanoESI source for ionization of polar metabolites. A DBDI source was also used as a post-ionization source to improve the ionization of apolar metabolites in cells that are difficult to ionize using ESI. The classes of identified metabolites can be altered from mostly polar to both polar and apolar to mainly apolar by increasing the voltage of the DBDI source from 0 to 3.2 kV. This study investigated the metabolites in plant cells (onion) and human cells (PANC-1). In ESI mode (3.5 kV), 50 compounds in onion cells and 40 compounds in PANC-1 cells were detected after optimization. In ESI (3.5 kV)-DBDI (2.6 kV) hybrid mode, an additional 49 compounds in onion cells and 73 compounds in PANC-1 cells were observed. This hybrid ionization source improves the coverage, ionization efficiency, and limit of detection of metabolites with different polarities, and could help to promote the rapid development of single-cell metabolomics.

In Chapter 5, an all-in-one 3D-printed ESI source was manufactured for single-cell analysis. This 3D-printed ionization source integrates the cell introduction system, metabolite extraction and ionization source into one unit, simplifying the process of single-

cell analysis and improving the reproducibility of measurement. We were able to successfully perform a high-throughput analysis for three different cancer cell types (around 17 cells/min). We showed the potential of 3D printing for single-cell analysis by using the t-SNE algorithm to distinguish between several cell types depending on selected features. 3D-printed ionization sources are more affordable, quicker to make, and more readily available than other ionization sources.

The findings of this thesis are summarized in Chapter 6, some unresolved questions are highlighted, and suggestions are made for future development in single-cell mass spectrometry.

In the appendix, a project that used ESI to reveal high levels of hydrogen peroxide ( $\text{H}_2\text{O}_2$ ) in pancreatic cancer cells is presented. As this project was conducted at the level of cell populations, it has been placed in the appendix rather than in the main text. This study revealed that the oncogenic KRAS mutation enhances the accumulation of  $\text{H}_2\text{O}_2$  in pancreatic cancer. We also discovered that high levels of  $\text{H}_2\text{O}_2$  impact cellular metabolites and enhance pancreatic cancer cell survival. These findings highlight the precise roles of  $\text{H}_2\text{O}_2$  in the development of pancreatic cancer, perhaps opening up new avenues for pancreatic cancer treatment.

# Zusammenfassung

Zelluläre Heterogenität ist für die physiologischen Funktionen von Organismen von grosser Bedeutung, und die genaue Interpretation der relevanten biologischen Mechanismen erfordert eine genaue Messung von Biomolekülen wie DNA, RNA, Proteinen und Metaboliten auf Einzelzellebene. Zelluläre Metaboliten reagieren am schnellsten auf Umwelt- und biochemische Veränderungen, sodass der Nachweis zellulärer Metaboliten ein entscheidender Schritt zur Bestimmung des physiologischen Zustands von Zellen ist. Die geringen Mengen und die strukturelle Vielfalt der Metaboliten in einzelnen Zellen sowie die großen Unterschiede im Gehalt der verschiedenen Metaboliten macht die Metabolomanalyse in einzelnen Zellen jedoch eine technischen Herausforderung.

Die Massenspektrometrie mit ihrer hohen Empfindlichkeit, guten Selektivität und großen dynamischen Bereich hat sich in den letzten Jahren in der Einzelzellanalyse durchgesetzt. Die Weiterentwicklung der Einzelzell-Massenspektrometrie ist untrennbar mit der Entwicklung von Ionisierungsquellen verbunden, und verschiedene Ionisierungsmethoden haben ihre eigenen Merkmale und können sich gegenseitig ergänzen.

In dieser Dissertation wurden selbstgebaute Umgebungsionisationsquellen zur Untersuchung der Einzelzellmetabolomik verwendet, wie eine dielektrische Barriereentladungsisolation (DBDI), eine hybride Ionisationsquelle, die Nanoelektrospray (nanoESI) und DBDI kombiniert, und eine 3D-gedruckte Ionisationsquelle.

In Kapitel 1 werden einige allgemeine Informationen über die Einzell-Massenspektrometrie vorgestellt.

In Kapitel 2 werden die Grundprinzipien der in dieser Arbeit verwendeten Methoden und Instrumente erläutert.

In Kapitel 3 wird eine markierungsfreie, schnelle Einzelzell-Analysemethode auf der Grundlage der Massenspektrometrie mit dielektrischer Barrierenentladung vorgestellt, mit welcher mehrere Metaboliten in Einzelzellen mit einem Durchsatz von 38 Zellen/Minute gleichzeitig nachgewiesen werden können. Mehrere Zelltypen (HEK-293T, PANC-1, CFPAC-1, H6c7, HeLa und iBAs) wurden erfolgreich differenziert. In Bauchspeicheldrüsenkrebszellen entdeckten wir Anzeichen für einen abnormalen Lipidstoffwechsel. Wir überprüften auch die Genexpression in einem Krebsgenom-Atlas-Datensatz und stellten fest, dass der mRNA-Spiegel eines wichtigen Enzyms der Lipidsynthese (ATP-Citrat-Lyase, ACLY) in menschlichen duktalem Adenokarzinomen der Bauchspeicheldrüse (PDAC) hochreguliert war. Außerdem wurde gezeigt, dass sowohl ein chemischer ACLY-Inhibitor als auch eine siRNA-Methode, die auf ACLY abzielt, die Lebensfähigkeit von PDAC-Zellen verringert. Diese Studie zeigte, dass ACLY ein potenzieller Angriffspunkt für die Behandlung von Bauchspeicheldrüsenkrebs sein könnte, da der Lipidgehalt in den behandelten Zellen erheblich reduziert wurde.

In Kapitel 4 wird eine nanoESI-DBDI-Hybridionisierungsquelle für die Einzelzellanalyse vorgeführt. Eine Kapillare mit einer 1  $\mu\text{m}$  i.d. Spitze wurde zur Probenahme in die Zellen eingeführt und dann direkt als nanoESI-Quelle für die Ionisierung polarer Metaboliten verwendet. Eine DBDI-Quelle wurde auch als Nachionisierungsquelle verwendet, um die Ionisierung von apolaren Metaboliten in Zellen zu verbessern, die mit ESI nur schwer zu ionisieren sind. Die Klassen der identifizierten Metaboliten können durch Erhöhung der Spannung der DBDI-Quelle von 0 auf 3.2 kV von überwiegend polar über sowohl polar als auch apolar bis hin zu überwiegend apolar verändert werden. In dieser Studie wurden die Metaboliten in Pflanzenzellen (Zwiebel) und menschlichen Zellen (PANC-1) untersucht. Im ESI-Modus (3.5 kV) wurden nach der

Optimierung 50 Verbindungen in Zwiebelzellen und 40 Verbindungen in PANC-1-Zellen nachgewiesen. Im ESI (3.5 kV)-DBDI (2.6 kV)-Hybridmodus wurden zusätzlich 49 Verbindungen in Zwiebelzellen und 73 Verbindungen in PANC-1-Zellen beobachtet. Diese hybride Ionisierungsquelle verbessert die Abdeckung, die Ionisierungseffizienz und die Nachweisgrenze von Metaboliten mit unterschiedlichen Polaritäten und könnte dazu beitragen, die rasche Entwicklung der Einzelzell-Metabolomik zu fördern.

In Kapitel 5 wurde eine All-in-One-3D-gedruckte ESI-Quelle für die Einzelzellanalyse hergestellt. Diese 3D-gedruckte Ionisationsquelle integriert das Zelleinführungssystem, die Metabolitenextraktion und die Ionisationsquelle in einer Einheit, vereinfacht den Prozess der Einzelzellanalyse und verbessert die Reproduzierbarkeit der Messungen. Wir konnten erfolgreich eine Hochdurchsatzanalyse für drei verschiedene Krebszelltypen durchführen (etwa 17 Zellen/min). Wir zeigten das Potenzial des 3D-Drucks für die Einzelzellanalyse, indem wir den t-SNE-Algorithmus verwendeten, um zwischen verschiedenen Zelltypen anhand ausgewählter Merkmale zu unterscheiden. 3D-gedruckte Ionisierungsquellen sind preiswert, schneller herzustellen und leichter verfügbar als andere Ionisierungsquellen.

Die Ergebnisse dieser Arbeit werden in Kapitel 6 zusammengefasst, einige ungelöste Fragen werden hervorgehoben, und es werden Vorschläge für die zukünftige Entwicklung der Einzelzell-Massenspektrometrie gemacht.

Im Anhang wird ein Projekt vorgestellt, bei dem mit ESI hohe Konzentrationen von Wasserstoffperoxid ( $H_2O_2$ ) in Bauchspeicheldrüsenkrebszellen nachgewiesen wurden. Da dieses Projekt auf der Ebene von Zellpopulationen durchgeführt wurde, wurde es nicht in dem Haupttext, sondern in den Anhang aufgenommen. In dieser Studie ergab sich, dass die onkogene KRAS-

Mutation die  $H_2O_2$ -Akkumulation in Bauchspeicheldrüsenkrebszellen erhöht. Wir entdeckten auch, dass hohe  $H_2O_2$ -Konzentrationen Auswirkungen auf zelluläre Metaboliten haben und das Überleben von Bauchspeicheldrüsenkrebszellen fördern. Diese Ergebnisse unterstreichen die genaue Rolle von  $H_2O_2$  bei der Entstehung von Bauchspeicheldrüsenkrebs und eröffnen vielleicht neue Wege für die Behandlung von Bauchspeicheldrüsenkrebs.

# Chapter 1

## 1. Introduction

In this dissertation, single-cell metabolomics is studied by home-built ambient ionization sources, including a dielectric barrier discharge ionization (DBDI) source, a hybrid ionization source combining nanoelectrospray (nanoESI) and DBDI, and a 3D-printed ionization source. The fundamentals and motivations of single-cell analysis are introduced in Section 1.1. The research contents and difficulties in single-cell analysis are presented in Section 1.2, and we will focus on single-cell metabolomics rather than other single-cell omics. In sections 1.3 and 1.4, the difficulties in single-cell analysis and the research progress of single-cell mass spectrometry are described. The aims and outline of this thesis are summarized in Section 1.5.

### 1.1 Why study single cells

Cellular heterogeneity exists between individual cells due to differences in intracellular gene expression levels, cellular physiological environment, cell age, and other factors that influence the phenotype of individual cells in culture.<sup>1</sup> Identifying these differences can reveal critical information. Traditional population measurements obscure information on intercellular heterogeneity, which does not yield the true chemical composition and content of individual cells.<sup>2</sup> In addition, rare cell types such as circulating tumor cells (CTCs) or cancer stem cells play significant roles in pathogenic mechanisms and early diagnosis of tumors. However, due to their

low abundance, bulk analysis hardly provides meaningful information for the study of rare cell types.<sup>3</sup> Single-cell analysis, on the other hand, can deliver a wealth of information for the studies of cell physiology and pathology.

## **1.2 What to study at single-cell level**

Various single-cell “omics” approaches have been developed, including single-cell genomics, transcriptomics, proteomics and metabolomics.<sup>4-6</sup> Compared to other single-cell “omics” methodologies, metabolomics provides the most rapid and dynamic information on cellular functions, owing to the dynamic response of the metabolome to the environment on a short time scale (seconds or less), its structural diversity, and the large dynamic range of metabolites.<sup>7-9</sup> Single-cell metabolomics focuses on the determination of small-molecule metabolites with molecular weights less than ~2 kD in specific cells, organs, and organisms, mainly including endogenous and exogenous small molecules (e.g., lactate, sugars, AMP, ADP, ATP, drugs and their metabolites and lipids).<sup>1</sup>

## **1.3 Difficulties in single-cell analysis**

However, single-cell metabolomics is challenging because of the low amounts of single-cell metabolites; for example, the volume of a single *E. coli* cell is around 1 fL, and the intracellular metabolite content is at the fg level, even for metabolites of the central metabolism that are present in high concentrations.<sup>10</sup> Furthermore, intracellular metabolites cannot be amplified and then detected, as is possible for intracellular DNA. Therefore, single-cell metabolomics

requires highly sensitive and selective analytical techniques. In addition, in order to increase the coverage of single-cell metabolomics analyses, quantitative or semi-quantitative analysis of as many cellular metabolites as possible is desirable.

## **1.4 Development of single-cell mass spectrometry**

The emergence of diverse single-cell analysis techniques has greatly promoted the development of single-cell research. The main techniques currently used for single-cell analysis include electrochemistry,<sup>11-13</sup> fluorescence microscopy,<sup>14-16</sup> vibrational spectroscopy,<sup>17-19</sup> capillary electrophoresis,<sup>20-21</sup> mass spectrometry<sup>22-26</sup> and so on.

Mass spectrometry is a well-suited assay for single-cell analysis, with high versatility, good sensitivity, fast analysis speed, wide dynamic range, and the ability to analyze thousands of compounds simultaneously. Since mass spectrometry detects the molecular weight of each compound, mass spectrometry-based single-cell analysis methods are universal and do not require fluorescent labeling or derivatization, and they are extensively used in single-cell metabolomics.

Currently, single-cell mass spectrometry methods based on different ionization techniques have been developed for single-cell metabolomics, including nanoelectrospray ionization (nanoESI)-based methods,<sup>24,27-28</sup> matrix-assisted laser desorption/ionization (MALDI)-based methods,<sup>29-31</sup> secondary ionization mass spectrometry (SIMS)-based methods,<sup>26,32-33</sup> and dielectric barrier ionization discharge (DBDI)-based methods.<sup>34-35</sup> These ionization methods have their own characteristics and can complement each other. Below, the corresponding mass spectrometric single-cell

analysis methods are described for each of these four ionization techniques.

### **1.4.1 ESI-based methods**

ESI is a "soft" ionization source with high ionization efficiency and has a wide range of applications in the life sciences.<sup>36</sup> NanoESI offers higher ionization efficiency and sample utilization compared to traditional ESI technology. NanoESI-based single-cell analysis methods generally use a probe or laser for sampling.<sup>24,37</sup>

Some very interesting methods are based on direct aspiration of liquid from certain parts of living cells by a microcapillary that can be moved with a manipulator in 3D with real-time observation under a microscope. After sampling, direct ionization can be performed by nanoESI. Masujima and co-workers have done pioneering work in this field,<sup>24,38-40</sup> developing a "live single-cell MS" (live MS) method and applying it to analyze differences in the distribution of subcellular metabolites in RBL-2H3 (rat leukemia cell line) (Figure 1.1a).<sup>24</sup> Subsequently, they have successfully applied live MS for the analysis of metabolites in plant cells<sup>39,41</sup> and CTCs.<sup>38</sup> This early research using live single-cell MS has inspired many subsequent studies. For example, Yang and co-workers developed a single-probe-based nanoESI source to enable real-time, *in-situ* single-cell metabolomics analysis. They successfully detected several cellular metabolites and low MW anti-cancer molecules, including paclitaxel, doxorubicin, and OSW-1 in single HeLa cells.<sup>42</sup> To achieve real-time analysis of suspended live single cells, they further developed a T-shaped probe and realized the analysis of single colon cancer cells (HCT-116) in suspension.<sup>43</sup> Using this approach, it was possible to track how the metabolites in HCT-116 cells changed after treatment with anticancer drugs. To analyze

metabolites at the subcellular level, Zhang and co-workers used a tungsten probe as a solid-phase microextraction (SPME) probe to directly sample and enrich metabolites in living cells followed by desorbing/ionizing the enriched metabolites from the tip of the tungsten probe for MS detection.<sup>44</sup> They successfully detected different types of metabolites, including 6 fructans, 4 lipids, and 8 flavone derivatives in single *Allium cepa* cells. To demonstrate the subcellular detection capability of this method, they used a nucleus dye (methylene blue) to stain onion epidermal cells. The stained nuclei and cytoplasm were then sampled and measured separately by ESI-MS, and it was found that the signal intensity of methylene blue in the nucleus was approximately 20x higher than that in the cytoplasm. In general, probe-based sampling methods are direct and can be performed *in situ*, but the complicated sampling operation limits the throughput and reproducibility of this method, and only some metabolites can be detected in individual cells.

Due to the complexity of the intracellular metabolome, nanoESI has also been coupled with separation techniques to reduce interferences between different compounds and improve detection sensitivity and coverage. Capillary electrophoresis (CE) is particularly well suited because only very small injection volumes of liquid sample are required.<sup>45-48</sup> Nemes and co-workers applied CE-ESI-MS to the metabolomic analysis in single cells in developing *Xenopus laevis* embryos (Figure 1.1b),<sup>49</sup> obtaining a limit of detection of ~5-10 nM (50-100 amol) for dual cationic-anionic analysis.<sup>50</sup> More recently, they achieved both single-cell proteomic and metabolomic analysis in *Xenopus laevis* embryos by CE-ESI-HRMS. After *in-situ* microprobe sampling, they tested the embryos' viability and found that they can still develop freely into visually normally behaving tadpoles.<sup>51</sup> Although still on the slow side in terms of throughput, CE-ESI-MS reveals a wealth of metabolite information in

single cells, paving the way for a better understanding of cell metabolism.

In addition to probe-based sampling methods, laser-based sampling approaches have been developed for nanoESI-based single-cell analysis. For example, laser ablation electrospray ionization (LAESI) is a typical laser-based method that utilizes an IR laser with a specific wavelength for desorption and ESI for post-ionization. Vertes and co-workers proposed *in-situ* analysis of individual cells by LAESI-MS at atmospheric pressure.<sup>37,52-53</sup> For example, they analyzed the metabolites in *Allium cepa*, *Narcissus pseudonarcissus* bulbs and *Lytechinus pictus* at the single-cell level, and also analyzed individual epidermal cells from different scale leaves in *A. cepa* bulbs simultaneously, to study metabolic differences.<sup>37</sup> Generally, LAESI uses an optical fiber to deliver the laser beam and is able to analyze large, single cells with an average volume of ~1 nL. However, only a small fraction of the samples is ionized due to the expansion of laser-ablated gaseous samples in three dimensions, which becomes very challenging for the analysis of small cells. Vertes and coworkers thus utilized a capillary to limit the expansion of the ablation plume, improving its overlap with the electrospray plume, which achieved higher ionization efficiency and lower detection limits when compared to conventional LAESI (Figure 1.1c).<sup>52</sup> Using this method, they measured hexose, disaccharide and a trisaccharide in single buccal epithelial cells (with diameters of 30-50  $\mu\text{m}$ , volumes of 14-65 pL/cell), and glycine, trimethylamine dimer, and lipids in individual sea urchin eggs (with diameters of 90-100  $\mu\text{m}$ , volumes of 400-500 pL/cell). These cells are larger than typical animal cells (with diameters of typically 10-30  $\mu\text{m}$ ), i.e., LAESI still needs to be improved in terms of sensitivity for single-cell detection.

An isolated measurement of a single cell or low-throughput measurements of several cells may have less biological significance, as hundreds or thousands of measurements are frequently required to generate statistically significant data in biology. Microfluidics-based methods are effective techniques for studying complex biological systems because of their low sample consumption, outstanding performance to handle trace liquids, and high throughput.<sup>54</sup> The channel size of a typical microfluidic device is around 10~100  $\mu\text{m}$ , which is close to the size of cells, and thus the range of operations and processes at the single-cell level can be performed efficiently in microfluidic chips.<sup>55</sup> To enable high-throughput analysis and to obtain biologically meaningful data, microfluidic techniques have been combined with nanoESI for single-cell analysis.<sup>56-60</sup> For example, Zhang and co-workers proposed a capillary microfluidics platform-based flow cytometry ESI-MS (CyESI-MS) technique to achieve high-throughput single-cell analysis (38 cells/min), cell type discrimination, and biomarker screening (Figure 1.1d).<sup>57-58</sup> Liu and co-workers combined nanoESI with microfluidic chips to identify 100 metabolites and 6 protein biomarkers in single cancer cells with a high throughput of 40 cells/min, and they successfully distinguished different cell types based on the information of simultaneously detected proteins and metabolites.<sup>59</sup> These methods open the door for higher throughput single-cell analyses, to obtain statistically significant data.

## 1.4.2 MALDI-based methods

Matrix-assisted laser desorption/ionization source (MALDI) is a soft ionization method used for investigating large molecules. MALDI-MS measurements require mixing the sample with a matrix and then irradiating the sample with a UV laser beam, usually in high vacuum. The analytes are then desorbed and ionized, and enter the mass spectrometer for detection. MALDI has been widely used in the field of single-cell analysis due to its high spatial resolution and sensitivity.<sup>25-26,29,32,61-64</sup> It is sensitive, fast, and is able to provide

simple mass spectra of the analytes even from complex mixtures. MALDI is a particularly powerful tool for lipid analysis.

Sweedler and co-workers used MALDI Fourier-transform ion cyclotron resonance (FTICR)-MS, to analyze over 30,000 individual rat cerebellar cells, and t-distributed stochastic neighbor embedding (t-SNE) to distinguish different subtypes of cells (Figure 1.2a).<sup>65</sup> In this work, FTICR-MS provided high mass resolution and mass accuracy, allowing 500 brain lipids to be assigned without the need for performing MS/MS. This is probably one of the largest numbers of cells analyzed in a single-cell MS experiment. In addition, they combined MALDI-MS and immunocytochemistry (ICC) to analyze lipids in astrocytes and neurons, revealing the lipid heterogeneity between these two cell types.<sup>63</sup> Although MALDI-MS enables high-throughput analysis of lipids for a variety of cells, it is usually not quantitative, and many low-molecular-weight metabolites are not detected due to interferences from the MALDI matrix. Sweedler *et al.* therefore coupled MALDI with CE-ESI-MS to effectively increase the throughput of single-cell analysis and improve the coverage of metabolites.<sup>61</sup>

To simplify the sample preparation process and improve the throughput of single-cell analysis, our group developed a high-density micro-array for mass spectrometry (MAMS) chips that can automatically generate pL aliquots that contain single cells from a cell suspension with the appropriate density (Figure 1.2b).<sup>66-68</sup> For example, we studied the ATP metabolism and glycolytic metabolic pathway in single yeast cells with MAMS-MALDI-MS, and also compared the results of single-cell analysis with those from population measurements.<sup>67-68</sup> Although the trends were consistent, there was a significantly higher variability in the results of the single-cell analysis that was not found in the population measurements, exactly as expected. In order to obtain multi-level information on

single cells, we also combined MALDI-MS with Raman and fluorescence microspectroscopy to monitor the growth of single cells of green algae.<sup>62,69</sup> These three methods applied to the same cells yielded complementary information and successfully identified metabolites such as ATP, ADP, astaxanthin, chlorophyll and  $\beta$ -carotene.

Mass spectrometry imaging (MSI) is a powerful and label-free technique for the untargeted investigating the spatial distribution of metabolites in single cells, and MALDI is the most useful and widespread ionization source type for MSI.<sup>70-73</sup> Although MALDI-MSI is a promising technique for chemical imaging of cell membranes, the ionization efficiency of MALDI is low. To address this problem, Dreisewerd and colleagues developed MALDI-2 to enhance the signal for membrane components other than some highly concentrated lipids via a postionization strategy (Figure 1.2c).<sup>70</sup> In contrast to prior photoionization investigations that were performed in high vacuum ( $p \leq 10^{-6}$  mbar),<sup>71-72</sup> MALDI-2 uses a pulsed ultraviolet (UV) laser beam that intercept the expanding particle plume in an  $N_2$  cooling gas environment.<sup>73-74</sup> By beam shaping and placing the focusing lens inside the MALDI ion source, the effective diameter of the primary laser beam reached 5  $\mu\text{m}$ . The technology has improved the sensitivity of some molecules such as drug compounds<sup>75</sup> and lipids,<sup>76</sup> and it recently achieved a pixel size of 600 nm with brain tissue by employing transmission-mode MALDI-2 MSI.<sup>64</sup> This technique could be a valuable new tool for cell biology and biomedical research.

**Figure 1.2.** Examples of MALDI-based single-cell mass spectrometry. (a) Single-cell MALDI-MS for lipid analysis. Reprinted with permission from ref. 65. Copyright 2019 American Chemical Society. ### 1.4.3 SIMS-based methods

Secondary-ion mass spectrometry (SIMS) is a surface analysis technique with high sensitivity and spatial resolution, which usually uses a high-energy primary ion beam to bombard the sample surface and sputter molecules off the sample surface to generate secondary ions that are characteristic for the chemical composition of the sample (Figure 1.3a).<sup>77-78</sup> Although SIMS is a relatively "hard" ionization source compared to MALDI and ESI, the greatest advantage of SIMS over other ionization sources is its extremely high spatial resolution, which can reach down to a few 10s of nm. SIMS is capable of analyzing small molecules such as metabolites, lipids, and

peptide fragments. Therefore, SIMS has been widely used for subcellular analysis and mass spectrometry imaging.<sup>26,32-33</sup> For example, the Ewing group has pioneered many SIMS imaging approaches for subcellular analysis. They used TOF-SIMS imaging to investigate changes in membrane structure driving the formation of lipid structural domains in mating *Tetrahymena thermophila*,<sup>79-80</sup> and the high sensitivity and resolution of SIMS contributed to the understanding of domains in cell membranes. In addition, they applied SIMS to image the fly brain and demonstrate that the drug methylphenidate alters the lipid composition. In order to find a correlation between the chemical and morphological structure of the brain, they used scanning electron microscopy (SEM) imaging along with SIMS imaging.<sup>81</sup> This discovery helped to clarify the relationship between biomolecular distribution and brain function. They also combined nanoSIMS with transmission electron microscopy (TEM) to visualize subvesicular compartmentalization and used it to identify the absolute concentration of dopamine in discrete vesicular compartments and whole vesicles.<sup>82</sup> This technique increases the possibility of absolute quantification and direct measurement of the specific contents of nanometer-scale organelles.

Although TOF-SIMS has a high spatial resolution for imaging single cells, it typically lacks the very high mass-resolving power, mass accuracy, and MS/MS capability necessary for the identification of biomolecules. Gilmore and co-workers have developed a 3D OrbiSIMS that combines a TOF-SIMS and an Orbitrap mass analyzer to achieve high-speed imaging, good resolution, and excellent sensitivity (Figure 1.3b).<sup>83</sup> The 3D OrbiSIMS is capable of visualizing exogenous and endogenous metabolites in 3D with subcellular resolution; for example, they imaged the distribution of neurotransmitters—gamma-aminobutyric acid (GABA), dopamine

and serotonin—in the mouse hippocampus (Figure 1.3c). They also putatively identified and mapped the subcellular distribution of 45 glycerophospholipids and 29 sulfoglycosphingolipids, and used tandem mass spectrometry to confirm the lipid identities. This technique captured hundreds of metabolites at subcellular resolution in a single measurement, resulting in a rich, multiplexed data set. It has the potential to shed light on basic biological processes.

**Figure 1.3.** Examples of SIMS-based single-cell mass spectrometry. (a) Principle of a SIMS measurement. A primary ion beam sputters the sample surface to generate secondary particles, including neutral particles and ions. The secondary ions are then extracted into the mass spectrometer. Reprinted with permission from ref. 77. Copyright 2019, The Royal Society of Chemistry. (b) Schematic of the 3D OrbiSIMS. Reprinted with permission from ref. 77. Copyright 2019, The Royal Society of Chemistry. (c) 3D OrbiSIMS mapping of GABA, dopamine, and serotonin in the cornu ammonis region of the mouse hippocampus. Reprinted with permission from ref. 83. Copyright 2017, Springer Nature. (d) Schematic of GCIB-SIMS imaging of HeLa cells. Reprinted with permission from ref. 85. Copyright 2020, The American Association for the Advancement of Science.

Another limitation of SIMS is that its analysis of biological samples produces obvious fragmentation, so molecules are hardly desorbed and measured intact. Gas cluster ion beams (GCIBs) have been used for SIMS-based MSI, because they produce less fragmentation than liquid metal ion guns but still provide excellent spatial resolution ( $<3\ \mu\text{m}$ ).<sup>78,84</sup> For example, Benkovic and co-workers performed low-chemical-damage, *in-situ*, three-dimensional chemical imaging analyses of intact molecular ions of metabolites using GCIB-SIMS (Figure 1.3d), such as their analysis of the de novo purine biosynthesis in single HeLa cells.<sup>85</sup>

#### 1.4.4 plasma-based methods

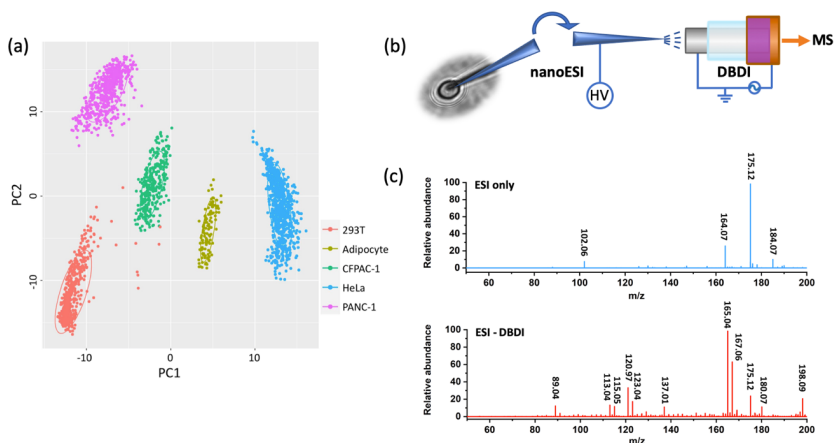

The low-temperature plasma (LTP)-based ionization source is highly efficient, easy to operate, and low cost. It is responsive to both polar and non-polar compounds, due to the presence of various reactive species in a plasma, such as electrons, ions, neutral atoms, excited states, radicals, and photons.<sup>86-89</sup>

The DBDI source, a type of LTP source, has been widely used in the field of mass spectrometry.<sup>90-93</sup> Our lab developed an active capillary plasma ionization based on the DBDI source, which guarantees almost 100% ion transport efficiency due to its direct connection to the inlet capillary of the mass spectrometer.<sup>94-102</sup> Since DBDI does not require a vacuum working environment and the associated complex sample preparation process, and its ionization process is soft, we have recently applied the DBDI source to the field of single-cell metabolomics.<sup>34-35</sup> We developed a high-throughput ( $\sim 38$  cells/min), label-free DBDI-MS-based single-cell analytical method. Based on the measured metabolites, we were able to distinguish multiple cell types, including HEK-293T, PANC-1, CFPAC-1, H6c7, HeLa and iBAs (Figure 1.4a). In addition, we observed an

abnormal lipid metabolism in pancreatic cancer cells by DBDI-MS, and then proposed and validated that it was caused by the dysregulation of ATP citrate lyase (ACLY). Therefore, ACLY was proposed to be a potential biomarker of pancreatic cancer.<sup>34</sup>

Metabolites in cells are diverse and vary in polarity. ESI is a powerful tool for the detection of polar metabolites, but it is not easy to ionize non-polar metabolites in single cells by ESI alone. Without information on non-polar metabolites, some important information may be overlooked in the study of single-cell metabolomics. In order to enhance the coverage of metabolites of different polarity in single cells, our lab reported a hybrid ionization source that combines ESI source and DBDI source to improve analyte coverage in single cells, mainly targeting non-polar metabolites (Figure 1.4b). In brief, the hybrid ionization source can operate in both ESI mode and ESI-DBDI hybrid mode. The ESI mode is mainly used to ionize polar metabolites, and nonpolar or less polar metabolites can be well ionized in the hybrid mode (Figure 1.4c). The classes of measured metabolites can be shifted from largely polar, to both polar and nonpolar, to mostly nonpolar by increasing the voltage of the DBDI source from 0 to 3.2 kV. In this work, we demonstrated the capability of the ESI-DBDI combination on human cells (PANC-1) and plant cells (onion). The method significantly increased the number of analytes detected from a single cell. Specifically, 40 metabolites in PANC-1 cells and 50 metabolites in onion cells were measured in ESI mode (3.5 kV). In hybrid mode, an additional 73 metabolites in PANC-1 and 49 metabolites in onion cells were detected.<sup>35</sup>

Although currently only a few groups use DBDI to analyze single cells, we believe it has the potential to be a very useful tool for single-cell metabolomics, due to its powerful ability to detect a wide range of various metabolites in cells.

**Figure 1.4.** Examples of plasma-based single-cell mass spectrometry. (a) Principal component analysis (PCA) of HEK-293T, PANC-1, CFPAC-1, H6c7, HeLa and iBas cells measured by DBDI-MS. ## 1.5 Aims and Outline of this Thesis

The study of metabolic heterogeneity in cells is essential to understanding the physiological functions of cells and the pathogenesis of diseases. Therefore, it is necessary to investigate single-cell metabolomics. In this dissertation, we applied home-built ambient ionization sources, including a DBDI source, a nanoESI-DBDI hybrid source and a 3D-printed ionization source, to investigate single-cell metabolomics.

In Chapter 1, some general information of single-cell mass spectrometry, focusing on the ESI-based methods, MALDI-based

methods, SIMS-based methods and plasma-based methods, are introduced.

The methods and instruments used in this thesis are described and explained in Chapter 2. Amongst them are a DBDI source, a nanoESI-DBDI hybrid source, a 3D-printed ionization source, as well as a cell introduction system and mass spectrometry in general.

In Chapter 3, a high-throughput, label-free and sensitive DBDI-MS platform was developed for the analysis of single-cell metabolites, with a throughput of approximately 38 cells per minute. Several cell types were successfully differentiated (HEK-293T, PANC-1, CFPAC-1, H6c7, HeLa, and iBAs) by the DBDI-MS platform. The abnormal lipid metabolism occurring in pancreatic cancer cells was investigated using the DBDI-MS platform.

In Chapter 4, a hybrid ESI + DBDI ionization source for single-cell analysis is proposed. Both ESI and hybrid modes can be used to operate the hybrid source. Polar metabolites are effectively ionized in ESI mode. Nonpolar or less polar metabolites show good ionization efficiency in hybrid mode. The classes of ionized metabolites in cells can be shifted from mainly polar to both polar and apolar to mostly apolar by gradually raising the DBDI voltage from 0 to 3.2 kV. Using this source, metabolites in human (PANC-1) and plant cells (onion) were investigated.

In Chapter 5, an all-in-one 3D-printed ESI source for single-cell analysis was developed. Using this 3D-printed ionization source, we performed a high-throughput analysis on three types of cancer cells (at a throughput of around 17 cells/min). We used the t-SNE algorithm to differentiate different cell types based on measured metabolites.

The conclusions of this thesis are given in Chapter 6, along with an outlook on the future trends of single-cell analysis.

The appendix contains a description of another project that did not use single cell mass spectrometry. The effect of high levels of

hydrogen peroxide ( $\text{H}_2\text{O}_2$ ) in pancreatic cancer cells was investigated by ESI-MS. This study revealed that the oncogenic KRAS mutation enhances the accumulation of  $\text{H}_2\text{O}_2$  in pancreatic cancer. We also discovered that high levels of  $\text{H}_2\text{O}_2$  affect cellular metabolites and enhances pancreatic cancer cell survival.

## Methods and Instrumentation

This chapter explains the basic principles of the methods and instruments used in this thesis.

### 2.1 DBDI-MS platform

The setup of DBDI-MS platform used in Chapter 3 includes a cell introduction system followed by the dielectric barrier discharge ionization source and a mass analyzer (Figure 2.1). The cell introduction system and the DBDI source are described in detail in the following sections.

**Figure 2.1.** The specific configuration and operation details of DBDI-MS platform, including: cell introduction system, a DBDI source, and an LTQ Orbitrap. Reprinted with permission from ref. 34. Copyright 2021, John Wiley & Sons.

#### 2.1.1 DBDI source

The home-built DBDI source from our lab has two electrodes (Figure 2.2), an inner electrode (grounded, stainless steel, ID: 0.6 mm and OD: 1.0 mm) and an outer electrode (high voltage, copper, ID: 1.55 mm, around a glass capillary). They are isolated by a glass capillary that acts as a dielectric barrier. A plasma is ignited inside the capillary when a high alternating current (AC) voltage is applied to the outer electrode. The ignition voltage of the plasma is around 2.0 kVpp. The operating AC voltage of the DBDI source is 2.2–3.2 kVpp. The discharge gas can be nitrogen, oxygen, carbon dioxide or air. The DBDI source is directly connected to the inlet capillary of the mass spectrometer, resulting in almost 100% ion transmission efficiency. The performance of the plasma source is affected by various operating parameters, including the applied high-voltage, discharge gas, frequency, and humidity.

**Figure 2.2.** The specific configuration of the home-built DBDI source.

### 2.1.2 Cell introduction system

The cell introduction setup was placed 2 mm in front of the DBDI source. As shown in Figure 2.1, the main parts of the cell introduction setup were 3 coaxial capillaries, two of which are fused silica

capillaries and one is a metal capillary. The inner capillary (193  $\mu\text{m}$  O.D., 75  $\mu\text{m}$  I.D.) was used to introduce a cell suspension from a sample vial. The intermediate capillary (350  $\mu\text{m}$  O.D., 250  $\mu\text{m}$  I.D.) was used to deliver MeOH which worked as extraction fluid. The exit end of the inner capillary was 4 mm shorter than that of the intermediate one (after optimization, Figure S3.3). When cells flowed out of the inner capillary and contacted with MeOH in the intermediate capillary, they were lysed and metabolites of the cells were extracted online by MeOH. Nitrogen, flowing through the outer metal capillary, was used as an auxiliary gas to help the solvent evaporate and cells fly into the DBDI.

### **2.1.3 Procedure for DBDI-MS Single Cell Analysis**

The DBDI-MS platform was composed of three main parts, including a cell introduction system, a DBDI source, and an LTQ Orbitrap (Figure 2.1). Before cell introduction, the inner capillary was thoroughly rinsed with a 140 mM  $\text{NH}_4\text{COOH}$  aqueous solution, and the intermediate capillary was thoroughly rinsed with MeOH until the background total ion chromatogram (TIC) is stable. As shown in Figure 2.1, the freshly prepared cell suspension was introduced into the inner capillary at a flow rate of 1  $\mu\text{L}/\text{min}$ , MeOH was introduced into the intermediate capillary at a flow rate of 11  $\mu\text{L}/\text{min}$ , the contact time between MeOH and cell suspension was less than 1s. Then the cell contents were ionized by DBDI and detected by a high-resolution Orbitrap mass spectrometer. After each measurement, all capillaries should be flushed with MeOH for 10 minutes at a flow rate of 7  $\mu\text{L}/\text{min}$ . The effects of lysis/extraction fluid on single-cell analysis and MeOH flow rate have been optimized (Figure S3.5 and Figure S3.6).

## 2.2 Hybrid nanoESI-DBDI source

The hybrid ionization source used in chapter 4 includes an electrospray ionization source followed by a home-built DBDI source (described in section 2.1.1) for post-ionization (Figure 2.3). The hybrid source has two modes: an “ESI mode” and a “hybrid mode” to detect intracellular metabolites with different polarities.

**Figure 2.3.** The specific configuration of hybrid ionization source. Reprinted with permission from ref. 35. Copyright 2022, American Chemical Society.

### 2.2.1 Home-built nanoESI source

A micropipette puller (P-1000, Sutter Instruments) was used to fabricate capillaries with a  $1 \mu\text{m} \pm 10\%$  tip ((B100-75-10, Sutter Instruments, California). The pulled capillaries were used as nanospray emitters. After the cell sampling, the tip of the pulled capillary was backfilled with  $2 \mu\text{L}$  of an assistant solvent. A platinum wire of  $200 \mu\text{m}$  in diameter and  $4 \text{ cm}$  in length was inserted into the pulled capillary to provide an electrical connection to the assistant solution close to the tip of the capillary, and a high direct current (DC) voltage ( $3.5 \text{ kV}$ ) was then applied to the electrode to generate an electrospray.

### 2.2.2 Single-Cell Sampling

In this work, the metabolites in human (PANC-1) and plant cells (onion) were investigated.

The epidermal cell layer of yellow onion bulbs was freshly peeled and placed on a glass slide, which was then placed on the platform of an inverted microscope (Nikon Eclipse Ti Light Microscope). Next, the pulled capillary was inserted into a capillary holder installed on a home-built manipulator. By adjusting the angle and distance between the tip of the capillary and the cell, the capillary was carefully inserted into the cell. The sampling process was observed by optical microscopy (as shown in Figure 2.4b). Around 30% of the cytoplasmic cell content was extracted by applying a negative pressure (-0.1 bar) applied by the syringe on the back of the capillary holder. After the cell sampling, the tip of the pulled capillary was backfilled with 2  $\mu\text{L}$  of an assistant solvent.

The subsequent single PANC-1 cell sampling method was the same as for single onion cells. Sampling images of PANC-1 cell and onion cell are shown in Figure 2.4a.

**Figure 2.4.** Sampling images of (a) PANC-1 cell and (b) onion cell. Reprinted with permission from ref. 35. Copyright 2022, American Chemical Society.

## 2.3 3D-printed ionization source

The 3D-printed ionization source used in chapter 5 was designed by Autodesk Inventor Professional 2021 (California, USA) and printed using “VisiJet M2R-CL” material (3D Systems, California, USA) by a professional 3D printer (ProJet MJP 2500, 3D Systems, California, USA). After printing, the 3D-printed ionization source was cleaned with steam and isopropanol, then dried for 24 hours in an oven before use. The technical drawing in Figure 2.5 outlines the details of the 3D-printed ionization design. In a nutshell, Figure 2.5 displays the three channels that make up the all-in-one 3D-printed ESI source. The external channel (1 mm I.D.) was used for gas introduction. MeOH was introduced as an extraction solution from the intermediate channel (300  $\mu$ m I.D.). The internal channel (200  $\mu$ m I.D.) of the 3D-printed ionization source was used to insert a fused silica capillary (193  $\mu$ m O.D., 75  $\mu$ m I.D.) to deliver cell suspensions.

Before cell introduction, the intermediate channel was carefully washed with MeOH, and the inner capillary was thoroughly rinsed with a 140 mM  $\text{NH}_4\text{COOH}$  aqueous solution until the background total ion chromatogram (TIC) remained stable. After optimization, the freshly prepared cell suspension was injected into the inner capillary at a flow rate of 1  $\mu\text{L}/\text{min}$ , while MeOH was introduced into the intermediate channel at a flow rate of 10  $\mu\text{L}/\text{min}$ . A DC voltage of 5.0 kV was applied to the MeOH through an electrode, creating a stable electrospray at the tip of the intermediate channel. As shown in Figure 2.5, the outlet end of the intermediate channel was 4 mm longer than the outlet end of the inner capillary. When the cell suspension exits the inner capillary and comes into contact with MeOH in the intermediate channel, the cells are lysed and metabolites in the cells are extracted into MeOH and nebulized into the mass spectrometer with the assistance of a flow of nitrogen sheath gas in the external channel. All channels were flushed with

MeOH for 10 minutes at a flow rate of 7 L/min following each measurement.

**Figure 2.5.** Schematic diagram of the 3D-printed ionization source.

## 2.4 Mass Spectrometer

The concept of separating ions and detecting them by mass-to-charge ratio ( $m/z$ ) is the foundation of mass spectrometry-based techniques. The separation of ions is accomplished using a magnetic, electric or field-free region, depending on the type of mass spectrometer being used. Different mass spectrometers have different strengths and weaknesses, and the choice of mass spectrometer can be made based on the application.

In this thesis, we used an LTQ Orbitrap mass spectrometer (Thermo Fisher Scientific, San Jose) for all the single-cell measurements. The LTQ Orbitrap is a hybrid mass spectrometer composed of a linear quadrupole ion trap (LTQ) and a high-

resolution Orbitrap. The basic principle of these two mass analyzers is thoroughly introduced in the following sections.

### 2.4.1 Linear Quadrupole Ion Trap

Ions can be stored, isolated, dissociated, and ejected using a linear quadrupole ion trap. It is made up of four hyperbolic rods that are separated into three sections (Figure 2.6). The ions are contained axially by applying various direct current (DC) voltages to the three sections on each rod and radially by applying radio frequency (RF) voltage to the opposing rod pairs. Through the exit rods, the ions can be radially ejected into the detector (slot in the center rods). The ions are ejected due to  $m/z$  selective instability caused by ramping up the RF voltage and applying additional AC voltage to the exit rods.<sup>103</sup>

**Figure 2.6** Basic design of the two-dimensional linear ion trap. Reprinted with permission from ref. 103. Copyright 2002, Elsevier.

The main benefit of a linear quadrupole ion trap is that it can confine a larger number of ions than a three-dimensional quadrupole ion trap can due to its physical size. As a result, the trapping device experiences the onset of space charge repulsion and

accompanying loss of mass resolution and change in mass assignment only with higher ion loading. The linear quadrupole ion trap retains nearly all of the useful operating characteristics of the three-dimensional quadrupole ion trap, including collisional focusing, resonant excitation and ejection, multiple stages of mass selectivity for tandem mass spectrometry ( $MS^n$ ), axial modulation, and mass resolution variation as a function of mass-selective ion ejection scanning rate.

The linear quadrupole ion trap from Thermo Fisher is known as the LTQ. The schematic diagram of the LTQ mass spectrometer has been shown in Figure 2.7. In short, the mass analyzer is kept free of big droplets and particles by the ion sweep cone. By adding a mass-dependent potential to the tube lens, the heated ion transfer capillary further desolvates the ions before focusing them on the skimmer. The lower-pressure ion guidance zone is separated from the high-pressure ion source interface (1 Torr) by the skimmer (50 mTorr). Three distinct ion guides (Q00, Q0, and Q1 lenses) focus on the ions such that they are directed toward the linear quadrupole ion trap. The conversion dynode and channel electron multiplier, which are off-axis to the mass analyzer, are where the ions are detected. To improve the mass resolution and sensitivity, helium is employed as the dumping gas in the mass analyzer cavity. This is due to ion collisions with helium, which decreases the kinetic energy of the ions, resulting in enhanced focus on the axis. Helium is also used as a collision gas for collision-induced dissociation.

**Figure 2.7** The schematic diagram of the LTQ mass spectrometer with typical operating voltages and pressures. Reprinted with permission from ref. 103. Copyright 2002, Elsevier.

## 2.4.2 Orbitrap

The high-resolution Orbitrap consists of a central electrode (spindle-shaped) surrounded by two outer electrodes (Figure 2.8). Ions are injected tangentially into the Orbitrap and rotate around the central electrode, along with radial and axial (along with the z-axis) harmonic oscillations. The oscillating ions generate image currents, which are detected by two external electrodes and converted to a spectrum of axial oscillations by the Fourier transform.<sup>104</sup> The standout characteristics of the Orbitrap are high resolving power and precise mass. The degree of each varies on the precise Orbitrap type and mode of operation. Mass precision is typically in the range of 0.5-3 ppm, and spectra are typically obtained at a resolving power of  $R = 20,000$ -200,000.

**Figure 2.8** A cut-away view of the Thermo Fisher Orbitrap™ mass analyzer. Ions are moving in spirals around a spindle-like-shaped central electrode (a) that creates an axial field gradient. An outer electrode (b) is split in half by an insulating ceramic ring (c). An image current induced by moving ions is detected via a differential amplifier between the two halves of the outer Orbitrap electrode. The  $m/z$  of different ions in the Orbitrap can be determined from respective frequencies of oscillation after a Fourier transform. Reprinted with permission from ref. 104. Copyright 2006, John Wiley & Sons.

### 2.4.3 LTQ-Orbitrap

In this thesis, a commercially available hybrid instrument, the LTQ Orbitrap from Thermo Fisher was used (Figure 2.9).<sup>105</sup> An atmospheric pressure ionization source, a linear quadrupole ion trap, a c-trap, and an Orbitrap comprise the LTQ Orbitrap. The C-trap is a bent RF quadrupole that captures and heats the ions before injecting them into the Orbitrap. Differential pumping is used along the LTQ and after the C-trap to achieve a vacuum in the Orbitrap of roughly  $10^{-10}$  mbar. The hybrid of LTQ and Orbitrap enables for simultaneous MS and  $MS^n$  investigations, such as MS in the ion trap and  $MS^2$  in the Orbitrap, as well as reverse. The low mass range is covered by the

LTQ, whereas the Orbitrap provide a high mass resolution and accuracy.

**Figure 2.9** Schematic diagram of the LTQ orbitrap hybrid mass spectrometer. The linear ion trap is followed by (a) a transfer octapole, (b) C-trap, (c) gate electrode, (d) trap electrode, (e) ion optics, to the (f) inner Orbitrap electrode, (g) outer Orbitrap electrode. # High-Throughput Single-Cell Mass Spectrometry Reveals Abnormal Lipid Metabolism in Pancreatic Ductal Adenocarcinoma

This Chapter is adapted from: Qinlei Liu, Wenjie Ge, Tongtong Wang, Jiayi Lan, Sandra Martínez-Jarquín, Christian Wolfrum, Markus Stoffel, Renato Zenobi. *Angew. Chem. Int. Ed.* **2021**, *60*, 24534-24542.

Even populations of clonal cells are heterogeneous, which requires high-throughput analysis methods with single-cell sensitivity. Here, we propose a rapid, label-free single-cell analytical method based on active capillary dielectric barrier discharge ionization mass spectrometry, which can analyze multiple metabolites in single cells at a rate of 38 cells/min. Multiple cell types (HEK-293T, PANC-1, CFPAC-1, H6c7, HeLa and iBAs) were discriminated successfully. We found evidence for abnormal lipid metabolism in pancreatic cancer cells. We also analyzed gene expression in a cancer genome atlas dataset and found that the mRNA level of a critical enzyme of lipid synthesis (ATP citrate lyase, ACLY) was upregulated in human pancreatic ductal adenocarcinoma (PDAC). Moreover, both an ACLY chemical inhibitor and a siRNA approach targeting ACLY could suppress the viability of PDAC cells. A significant reduction in lipid content in treated cells indicates that ACLY could be a potential target for treating pancreatic cancer.

### 3.1 Introduction

There are differences between individual cells, and even in the same cell population, cell heterogeneity exists.<sup>106</sup> Among the reasons are genetic differences and stochastic processes that occur in the cellular metabolism.<sup>1</sup> Since population measurements conceals information about the heterogeneity between cells, it is important to have sensitive analytical methods that afford the accurate chemical composition and contents of single cells. In addition, rare cell types including circulating tumor cells, cancer stem cells, invariant natural killer T cells, antigen-specific T cells, etc., play significant roles in pathogenic mechanisms, early diagnosis of tumor, and angiogenesis in cancer and other diseases.<sup>107-108</sup> In order to understand the results of these genetic differences and stochastic processes in individual cells more deeply and faithfully reflect the role that cells play in the regular operation of biological systems in terms of structure and function, it is necessary to analyze and study the composition and chemical content of cells at the single-cell level.

The concept of single-cell analysis has received widespread attention in recent years and has important applications.<sup>109-111</sup> Various single-cell omics technologies have emerged, including single-cell genomics, transcriptomics, proteomics and metabolomics. Also, Single-cell omics technologies have been applied to reveal metabolic heterogeneity of cells.<sup>112</sup> Compared to single-cell genomics, transcriptomics, and proteomics, single-cell metabolomics provides more rapid and dynamic information of cell function. For example, a deregulated metabolism is a hallmark of cancer cells.<sup>113</sup> Specifically, a dramatic increase of the de novo biosynthesis of fatty acids is generally observed in tumor cells. The increased capacity for generating lipids not only facilitates the formation of lipid bilayers but also enables the tumor cells to modulate their specific signaling transduction and cope with

oxidative stress.<sup>114</sup> For example, pancreatic ductal adenocarcinoma (PDAC) is one of the most lethal cancers with only around 9 % 5-year survival rate.<sup>115</sup> Accumulation of fatty acids was reported to correlate with PDAC initiation and metastasis in a PDAC mouse model,<sup>116</sup> indicating that lipid metabolism may be dysregulated in PDAC. Cancer cells are highly heterogeneous and exhibit phenotypic diversity, and the heterogeneity of cancer is closely related to the pathogenesis of cancer.<sup>117</sup> Single-cell analysis can accurately characterize the heterogeneity of cancer, thereby providing cancer treatment strategies.<sup>118</sup>

Single-cell analysis is challenging because intracellular biochemical reaction rates are fast, intracellular composition is very complex, the sample size is very small, some compounds are present only at the trace level, may have poor stability, and may be structurally similar. Studying the biological properties of single cells requires analytical techniques with high sensitivity, the ability to analyze ultra-small samples, good selectivity, and fast response. Since mass spectrometry has high sensitivity and selectivity, it holds great promise as an effective technique for single-cell metabolomics analysis. Numerous mass spectrometric techniques have been developed to elucidate the molecular profiles at the cellular level, including secondary ion mass spectrometry (SIMS),<sup>26,32,119</sup> matrix-assisted laser desorption/ionization mass spectrometry (MALDI-MS)<sup>63,120-121</sup> and electrospray ionization mass spectrometry (ESI-MS).<sup>41,122-123</sup> There are many ESI-based single-cell analytical methods, such as laser ablation-ESI-MS,<sup>53</sup> single probe ESI,<sup>123</sup> and T-probe ESI,<sup>124</sup> capillary electrophoresis-ESI-MS<sup>125-126</sup> and so on, however, most of them are low-throughput. Mass Cytometry (CyTOF) is a powerful plasma-based single-cell analysis tool that combines inductively coupled plasma mass spectrometry and flow cytometry.<sup>127-128</sup> CyTOF can simultaneously detect multiple cell surface protein markers at the single-cell level, but does not detect

low molecular weight metabolites. Recently, ESI-MS has been used as a flow cytometry detector to achieve high-throughput analysis of single-cell metabolites.<sup>57,59</sup> To widen the metabolome coverage, alternative ionization methods are useful.

Here we therefore explore the use of dielectric barrier discharge ionization (DBDI) for single-cell metabolomics. DBDI operates without auxiliary reagents and at atmospheric pressure, is easy to miniaturize, easy to operate, cheap and efficient, and has been used for the ionization of small molecular weight metabolites in recent years.<sup>86,129-130</sup> The DBDI-MS method introduced here has similar performance in terms of throughput, sensitivity, and the ability to distinguish cell types than the recently reported CyESI-MS methodology.<sup>57,59</sup> However, compared to other ionization methods, DBDI has some unique properties, for example, it is less affected by matrix effects and ion suppression than ESI,<sup>92,131</sup> it can analyze polar and nonpolar compounds simultaneously, and does not need vacuum condition.<sup>86,132</sup> Very recently, we have applied an ESI—DBDI combination source to single plant cell analysis.<sup>35</sup> Compared to ESI, a 2-fold increase in the number of visible metabolites was observed in the combination source.

In this work, we propose a high-throughput and label-free single-cell analytical method based on an active capillary DBDI source,<sup>133</sup> where the ionization takes place inside a capillary that is directly connected to the MS inlet. This dramatically increases robustness and ion transmission into the MS. The DBDI-MS platform (Figure 3.1) used in this work can analyze multiple metabolites in a single cell at the same time, including organic acids, carbonyl compounds, heterocyclic organic compounds and lipids, and can detect around 38 cells per minute. The proposed DBDI-MS platform was able to discriminate multiple cell types (293T, PANC-1, CFPAC-1, HeLa and iBAs) based on their metabolic profile. Moreover, the abnormal lipid

metabolism in pancreatic cancer cells was observed by using the DBDI-MS platform. As one of the major components involved in fatty acyl chain biosynthesis, the enzyme ATP citrate lyase (ACLY) is frequently upregulated in tumor cells.<sup>134</sup> Recently, it has been shown that ACLY is critical for the initiation of PDAC in pancreatic cancer animal model, as ACLY ablation attenuated the acinar-to-ductal metaplasia (ADM).<sup>135</sup> However, the expression levels and potential role of ACLY were not fully elucidated in established PDAC. Here, we propose that the expression levels of ACLY are related to the abnormal lipid metabolism in established PDAC. The DBDI-MS platform specifically detected the redistribution of lipids in PDAC cells after treating them with different dosages of specific ACLY inhibitor but not in PDAC cells treated with a canonical anticancer drug (gemcitabine) or DMSO. Furthermore, both specific chemical inhibitor or siRNA approach targeting ACLY could reduce the cell viability in PDAC cells, indicating the tumor-promoting effect of ACLY in established PDAC cells.

**Figure 3.1.** Schematic of the DBDI-MS platform. Cells are lysed by MeOH in the cell introduction system, and the metabolites in the cells are ionized by DBDI source.

## **3.2 Experimental Section**

### **3.2.1 Chemicals, Materials and cells**

Methanol (99.9%), ammonium acetate, ammonium formate (>99.0%), gemcitabine, SB204990 and dimethylsulfoxide (DMSO) were purchased from Sigma-Aldrich Chemie GmbH (Buchs, Switzerland). Phosphate Buffer Saline (PBS) were purchased from Thermo Fisher Scientific (Buchs, Switzerland). Fused silica capillary tubes were purchased from Polymicro Technologies (BGB Analytik AG, Switzerland). HEK-293T, HeLa, PANC-1, CFPAC-1 and preadipocyte were purchased from ATCC. H6c7 was purchased from Kerfast.

### **3.2.2 Cell culture**

CFPAC-1 was maintained in RPMI-1640 medium supplemented with 10% (v/v) fetal bovine serum and 1% Penicillin-Streptomycin (P/S). PANC-1, HEK-293T and HeLa were grown in DMEM with 10% (v/v) fetal bovine serum and 1% Penicillin-Streptomycin (P/S). H6c7 was maintained in a keratinocyte serum-free medium following the manufacturer's instructions. Immortalized brown adipocytes (iBAs) were derived from the differentiation of preadipocytes. Preadipocytes were cultured in DMEM with 10% fetal calf serum (FCS) and 1% P/S. In order to induce adipogenic differentiation, preadipocytes were grown to confluence on collagen-coated tissue culture plates and maintained for another 2 days. By adding 0.25 mM IBMX, 0.5  $\mu$ M dexamethasone, 10 nM insulin, 62.5  $\mu$ M indomethacin, and 0.5 nM T3 in full medium, preadipocytes were induced to differentiate into immortalized brown preadipocytes. After 24 h, the medium was exchanged for full medium plus 20 nM insulin and 1 nM T3. This medium was changed

every 2 days. Cells were analysis after 5 days of induction of differentiation. All cells were grown at 37°C in the humidified incubator (Thermo Fisher Scientific) with 5% CO<sub>2</sub>.

### **3.2.3 Drug treatment of PANC-1 and CFPAC-1 cells**

PANC-1 and CFPAC-1 cells plated in a culture dish and maintained with normal full medium until the cell confluent reaches 80%. Gemcitabine (sigma, cat# G6423) and SB204990 (sigma, cat# SML2829) were dissolved in DMSO (Sigma, cat# D4540), diluted into full medium at the indicated concentration and then incubated with PDAC cells for 48 hours.

### **3.2.4 Cancer Genome Atlas (TCGA) dataset analysis**

ACLY expression data of normal pancreatic tissues (GTEx; n = 167) and pancreatic ductal adenocarcinoma (TCGA-PDCA; n = 178) were downloaded from UNSC Xena (<https://xena.ucsc.edu/>). Differential expression analysis was performed using DESeq2. Gene Set Enrichment Analysis (GSEA v3.0) of GO biological processes was performed on normalized counts (PMID: 16199517).

### **3.2.5 qPCR**

Total RNA was isolated with Trizol following the manufacturer's protocol (Sigma, Cat# T9424). The resulting RNA was treated with DNase I (Thermofisher Scientific, Cat# AM1906). Then the RNA was reverse transcribed using High-Capacity cDNA Reverse Transcription Kit (Thermo Fisher Scientific, Cat# 4368813) by using random primers. Quantitative PCR was performed by KAPA SYBR FAST qPCR assay (Sigma, Cat# KK4611) in an LC480 II Lightcycler

(Roche). Results were normalized to human *36B4* mRNA levels. Primers: human ACLY forward (5'-3'): GATTTTGCGGGTTCGTCG, human ACLY reverse (5'-3'): GCTTGACTACCAAGTTCTGGC. Human *36B4* forward (5'-3'): GGCGCTACTTCTTCTCCTT. Human *36B4* reverse (5'-3'): TCGTAAATCATGGCCTGCAC.

### **3.2.6 Immunoblot (IB)**

PDAC or H6c7 cells were lysed in RIPA buffer (150 mM sodium chloride, 50 mM Tris-HCl pH=7.4, 0.1% SDS, 1 mM EDTA, 1% NP-40, 0.5% sodium deoxycholate) freshly supplied with protease inhibitors cocktail (Roche, cat#11873580001) and PhosSTOP (Roche, cat# 04906837001). The protein concentration was determined using the Bradford protein assay (abcam, cat# bfu051). The same amount of proteins was subjected to 10% SDS-PAGE analysis. The immune complex was detected by the ECL kit (Thermo Scientific). Phos-AKT (S473, cell signalling, cat#4060S), total AKT (Cell signalling, cat# 9272S), phos-p70 S6K (T389, Cell signalling, cat#9206S), total p70 S6K (Cell signalling, cat#9202S) and GAPDH (sigma, cat# G9545) were diluted at 1:1000 in 1x TBS buffer (pH:7.6). The amounts of protein were quantified by Image J software.

### **3.2.7 Determination of cell viability by MTT assay**

Cell viability was determined by MTT [3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyl-2H-tetrazoliumbromid] (Sigma, Cat# M5655) assay after transfecting cells with siRNA control (Horizon, cat# D-001810-10-05) or siRNA-ACLY (Horizon, cat# L-004915-00-0005) for 72 hours. Briefly, MTT solution in 1x PBS was added to each well of 96 well-plate at the final concentration of 0.5 mg/mL.

The plate was protected from light and incubated for 3 hours at 37 °C. The medium was then aspirated and the dark-blue formazan was dissolved with DMSO. Optical density was measured with a spectrometer at 490 nm. The raw luminescence data were normalized to the siRNA control.

### **3.2.8 Preparation of Cell Suspensions**

Before starting the experiment, DMEM was removed by centrifugation (1000 rpm, 4 minutes), and the cells were resuspended in PBS. Then the cells were centrifuged again (1000 rpm, 4 minutes) to remove PBS, and resuspended in 140 mM NH<sub>4</sub>COOH solution. The effect of solvent of cells has been optimized (Figure S3.2).

### **3.2.9 Cell Introduction System**

The cell introduction setup was placed 2 mm in front of the DBDI source. As shown in Figure S3.1, the main parts of the cell introduction setup were 3 coaxial capillaries, two of which are fused silica capillaries and one is a metal capillary. The inner capillary (193 μm O.D., 75 μm I.D.) was used to introduce cell suspension from a sample vial. The intermediate capillary (350 μm O.D., 250 μm I.D.) was used to transport MeOH which worked as extract fluid. The exit end of the inner capillary was 4 mm shorter than the intermediate one (after optimization, Figure S3.3). When cells flowed out of the inner capillary and contacted with MeOH in the intermediate capillary, the cell was lysed and metabolites of the cells were extracted by MeOH online. Nitrogen, carried in the outer metal capillary, was used as auxiliary gas to help solvent evaporate and cells fly into the DBDI.

### **3.2.10 Ionization Source**

An active capillary plasma ionization source (based on a dielectric barrier discharge ionization) was used to ionize single cells in this study.<sup>133</sup> As shown in Figure S3.1, the DBDI has two electrodes, an outer electrode (high voltage, copper, ID: 1.55 mm, surrounding the glass capillary) and an inner electrode (ground, stainless steel, ID: 0.6 mm and OD: 1.0 mm). They are separated by a glass capillary which is the dielectric barrier. When a high AC voltage (2.6 kVpp, 47 kHz) is applied to the outer electrode, the plasma will be ignited inside the capillary. The voltage of DBDI has been optimized (Figure S3.4).

### **3.2.11 Procedure for DBDI-MS Single Cell Analysis**

The DBDI-MS was composed of three main parts, including a cell introduction system, a DBDI source, and an LTQ Orbitrap (Figure S3.1). Before cell introduction, the inner capillary was thoroughly rinsed with a 140 mM  $\text{NH}_4\text{COOH}$  aqueous solution, and the intermediate capillary was thoroughly rinsed with MeOH until the background total ion chromatogram (TIC) is stable. The freshly prepared cell suspension was introduced into the inner capillary at a flow rate of 1  $\mu\text{L}/\text{min}$ , MeOH was introduced into the intermediate capillary at a flow rate of 11  $\mu\text{L}/\text{min}$ . Then the cell contents were ionized by DBDI and detected by a high-resolution Orbitrap mass spectrometer. After each measurement, all capillaries should be flushed with MeOH for 10 minutes at a flow rate of 7  $\mu\text{L}/\text{min}$ . The effects of lysis/extraction fluid on single-cell analysis and MeOH flow rate have been optimized (Figure S3.5 and Figure S3.6).

### 3.2.12 Mass Spectrometry

Mass spectra were acquired in positive ion mode, with an LTQ Orbitrap mass spectrometer (Thermo Fischer Scientific, San Jose, U.S.A.), in fullscan mode at a resolution of 30,000 FWHM (at  $m/z$  400) with a mass tolerance specified to be  $< 10$  ppm. The mass-to-charge range was set to 100–1000, capillary voltage is 50 V, tube lens voltage is 120 V, capillary temperature is 320°C, AGC target =  $10^6$ . Mass spectra were acquired using 1 microscans and a maximum injection time of 10 ms.

### 3.2.13 Data analysis

The MS raw data generated from the mass spectrometer was recorded with Xcalibur™ version 2.2 software (Thermo Fisher Scientific, San Jose, U.S.A.). The MSConvert software (ProteoWizard, v3.0)<sup>136</sup> was used to convert MS raw data (.raw) to mzXML format. The converted mzXML format file is imported into Matlab (R2019b version, MathWorks, Natick, MA), and preprocessed using self-developed Matlab code. In short, the peaks were selected from the overall averaged spectrum of the spectra obtained during the measurement. The picked peaks were used to centroid the collected data, and then a .csv file containing the peak intensity of each scan was generated for each collected MS data set.

PC(34:1) and PC(32:1) were selected as the markers for the successful detection of single cells, thereby extracting all ion signals related to single cells. Ion signals related to single cells with a signal-to-noise ratio (S/N ratio) greater than 3 and occurrence frequency greater than 30% in all cells were kept for further analysis. These selected target ions and their intensity in each pulse peak represented the metabolic profile of each single cell. Statistical analysis was conducted using R (v4.0.2). Signal intensities were

normalized against total ion count and then log 2 transformed. Based on the acquired metabolites information, principal component analysis (PCA) analysis and t-distributed stochastic neighbor embedding (t-SNE) were used for the visualization of single cells, heat maps were used to show the expression levels of metabolites in different cells. The two-tailed student's t-test was used to evaluate the statistical significance level (P-value) of single-cell metabolism information between different cell lines, which was displayed in the volcano plots. Violin plots were used to show the changes in lipids distribution of cells after different treatments.

The peak assignments were done by comparing the observed mass with the theoretical mass in the online databases, including Human Metabolome Database (<http://www.hmdb.ca/>), LIPID MAPS (<http://www.lipidmaps.org>) and METLIN metabolite database (<https://metlin.scripps.edu/>).

### **3.3 Results and Discussion**

#### **3.3.1 Feasibility of single cell DBDI-MS**

Since DBDI-MS has not previously been used for single-cell analysis, we conducted preliminary experiments to demonstrate its feasibility. A PANC-1 cell suspension (at a flow rate of 1  $\mu\text{L}/\text{min}$ ) and MeOH (at a flow rate of 11  $\mu\text{L}/\text{min}$ ) were introduced into the DBDI source via a home-built cell introduction system (Figure S3.1). As presented in Figure 3.2a, signal pulses appeared in the total ion chromatogram (TIC) when the DBDI source was on, but when it was off, even if the cell suspension was introduced into the DBDI source, there was no signal in the TIC. In order to demonstrate that the detected signals came from cells rather than from other substances, the peaks at  $m/z$  760.5851 (assigned to glycerophosphocholine (PC)

34:1) and  $m/z$  732.5538 (assigned to PC 32:1), which are components of cell membranes, were chosen as markers of cells passing through the DBDI. It can be seen from Figures 3.2b and c that the positions and frequency of  $m/z$  760.5851 and  $m/z$  732.5538 peaks matched with the TIC. Figures 3.2d and 3.2e display that with the DBDI switched on, there were obvious lipid peaks in the  $m/z$  700- $m/z$  900 region, but there were no lipid peaks when the DBDI was turned off. The results suggest that DBDI-MS is able to detect single cells.

**Figure 3.2.** PANC-1 cell analyzed by DBDI-MS. (a) Total ion chromatogram (TIC), (b) extracted ion chromatogram (EIC) of  $m/z$  760.5851 and (c) EIC of  $m/z$  732.5538 acquired in DBDI on and off modes. (d) mass spectrum in DBDI off mode, and (e) mass spectrum in DBDI on mode. The asterisk (\*) indicates electronic noise in the spectra.

The optimization of experimental conditions for single-cell analysis are described in detail in section 2 of the SI (Figures S3.2-S3.6).

To further evaluate the performance of DBDI-MS, analysis of different cell suspensions was carried out (in section 3 of the SI, Figures S3.7-S3.9), including PANC-1 cells, CFPAC-1 and H6c7 cells. In order to further prove that the results obtained were from single cells instead of cell clusters, the cell suspension was sequentially diluted with ammonium formate to  $5 \times 10^3$ ,  $1 \times 10^4$ ,  $2 \times 10^4$ ,  $3 \times 10^4$ ,  $4 \times 10^4$ ,  $5 \times 10^4$  cells/mL and then measured by DBDI-MS. To facilitate the calculation of cell concentration, the flow rate of the cell suspension during the entire experiment was set to 1  $\mu$ L/min. The results are summarized in Table 3.1, Table S3.1 and Table S3.2. As shown in Table 3.1, Table S3.1 and Table S3.2, the number of peaks per minute matched well with the cell concentration, and the number of detected cells were essentially the same as the calculated number of cells, which indicates that most cells were monodisperse and detected separately. However, when the cell concentration was  $\geq 5 \times 10^4$  cells/mL, we found that there were overlaps between the pulsed signals, and even the capillary used to introduce the cells was sometimes blocked. Therefore, the cell concentration used during the entire experiment was controlled to  $< 5 \times 10^4$  cells/mL. The above results prove that our method is high-throughput and able to detect metabolites with single-cell resolution.

**Table 3.1.** Comparison between the calculated and the detected number of PANC-1 cells at different densities of the cell suspension.

Cell density, cells mL <sup>-1</sup>	Calculated cell number [min]	Detected cell number [min]					Average detected cell number [min]
5 x 10 <sup>3</sup>	5	3	6	6	4	4	4.6
1 x 10 <sup>4</sup>	10	8	8	9	9	11	9
2 x 10 <sup>4</sup>	20	19	23	19	18	17	19.2
3 x 10 <sup>4</sup>	30	29	30	26	27	24	27.2
4 x 10 <sup>4</sup>	40	39	37	38	36	38	37.6

### 3.3.2 Metabolite Profiling and Discrimination of Cell Type.

In positive ion mode, approximately 179 peaks indicating metabolites in the  $m/z$  range between 100–1000 were detected in PANC-1 cells. These metabolites can be classified as organic acids, carbonyl compounds, heterocyclic organic compounds and lipids.

The details of the detected metabolite classification are shown in Table S3.3. Because there is only limited cell lysis during the brief contact with the MeOH flow (see Figure S3.1), the extracted metabolites originate mainly from the cell membranes, i.e., most of them are lipids. Since there are lots of reactive species in the plasma, different product ions were generated. In addition to common product ions such as  $[M+H]^+$ ,  $[M+Na]^+$ , there were also  $[M+H-H_2O]^+$ ,  $[M+H-2H_2O]^+$  and  $[M+NH_4]^+$  produced. The tandem MS information can be found in Figure S3.10.

Cell metabolites are potential biomarkers to distinguish cells. To test if our DBDI-MS could be applied to profile cell types, we measured five different kinds of cells, 293T, PANC-1, CFPAC-1, HeLa and iBAs by DBDI-MS. After obtaining metabolic information,

principal component analysis (PCA) (Figure 3.3a) and t-distributed stochastic neighbor embedding (t-SNE) (Figure S3.11) were used to separate cell types, which showed that single-cell metabolite information could successfully distinguish cell types. The specific details of the analysis for the metabolic profiles are described in section 1 of the SI. The heat map (Figure 3.3b) shows the relative intensities of metabolite ions from each cell. This information indicates that the types of single-cell metabolite profiles between different cells are significantly different, and single-cell metabolic information is adequate for cell discrimination.

All the above results showed that the DBDI-MS platform is sensitive, accurate and specific to detect a variety of metabolites.

**Figure 3.3.** Discrimination of cells by DBDI-MS platform. (a) Principal component analysis (PCA) of five cell types. (b) Heatmap of the single-cell metabolite in five cell types.

### 3.3.3 Single-Cell DBDI-MS Metabolic Profile Identify Deregulated Lipid Metabolism in PDAC Cells

Lipid metabolism is critical for cancer development, but the study on the level of lipid metabolism in PDAC cells is still very limited. Thus, we compared the metabolites of PDAC cells and ductal epithelial cells H6c7. By comparing the mass spectral profiles of PANC-1, CFPAC-1 and H6c7 (Figures 3.4a, b and c), we found that most of the detected compounds are phospholipids. Phospholipids are the main components of cell membranes, and their content in cells is high. In the lower mass range ( $m/z < 400$ ), PANC-1 and CFPAC-1 contained hexanoylcarnitine, which was not detectable in H6c7. In the higher mass range ( $m/z > 400$ ), the most abundant lipids in PANC-1, CFPAC-1 and H6c7 were PC(32:1), PC(34:1), PC(36:2) and PC(38:5), but their distribution was slightly different. As shown in Figures 3.4a, b, c and S4.12, in PANC-1 and CFPAC-1, PC (34:1) is the most abundant lipid, its intensity at  $m/z$  760.58 being higher than that of PC (36:2) ( $m/z$  786.60). However, in H6c7, PC (36:2) is the most abundant lipid, with an intensity of PC (34:1) ( $m/z$  760.58) lower than that of PC (36:2) ( $m/z$  786.60). As shown in Figures 3d, e, f and g, the content of PC(32:1), PC(34:1), PC(36:2) and PC(38:5) is higher in pancreatic cancer cell types (PANC-1 and CFPAC-1) than that in pancreatic ductal epithelial cells (H6c7). In addition to these lipids that occur in all three types, each of the cell also contained some unique lipids. For example, PC (0-36:1) and PS (40:3) were only detected in CFPAC-1, and TG (48:2) was only detected in H6c7.

The heat map in Figure S3.13 shows the normalized intensities of assigned metabolites from each cell, and significant differences are seen for some metabolites. In the volcano plots, differentially expressed features in the two pancreatic cancer cell lines (PANC-1, CFPAC-1) and the corresponding normal cell line (H6c7) are visualized. According to Figure 3.4h, several amino acids and lipids,

for example, *N*-lactoyl-methionine ( $m/z$  239.1061,  $[M+NH_4]^+$ ), hexanoylcarnitine ( $m/z$  260.1856,  $[M+H]^+$ ), MG(18:0) ( $m/z$  381.2981,  $[M+Na]^+$ ) and PS(30:2) ( $m/z$  686.4395,  $[M+H-H_2O]^+$ ) exhibited clear statistical differences between PANC-1 and H6c7 cells. As shown in Figure 3.4i, the metabolites with statistical differences between CFPAC-1 and H6c7 cells were also amino acids and lipids, for example, PC (34:1) ( $m/z$  782.5660,  $[M+Na]^+$ ), *N*-lactoyl-methionine ( $m/z$  239.1061,  $[M+NH_4]^+$ ) and hexanoylcarnitine ( $m/z$  260.1856,  $[M+H]^+$ ).

To further estimate the potential of DBDI-MS in clinical applications, we carried out an analysis of a mixed cell suspension composed of PANC-1, CFPAC-1 and H6c7 cells, to simulate potentially cancerous tissues of PDAC patients. Based on their characteristic single-cell metabolite profiles acquired by DBDI-MS, DBDI-MS can specifically and high-throughput identify different cell types in a cell mixture (Figure 3.4j) PANC-1 cells, CFPAC-1 cells, H6c7 cells and the cell mixture can be separated by t-SNE (Figure 3.4k), and cells from the mixture each fall into a specific group, which makes it possible to blindly identify cells from a mixture.

It can be seen that the types, content and distribution of lipids in pancreatic cancer cells and normal ductal cells are different, and that the abnormal lipid metabolism in pancreatic cancer cells can be clearly observed by DBDI-MS.

**Figure 3.4.** Assignment of cellular metabolites and discrimination of PDAC and H6c7 cells. (a) Typical PANC-1 single-cell mass spectrum. (b) Typical CFPAC-1 single-cell mass spectrum. (c) Typical H6c7 single-cell mass spectrum. (d-g) Normalized intensity of PC(32:1), PC(34:1), PC(36:2) and PC(38:5) in PANC-1, CFPAC-1 and H6c7 cells. (h) Volcano plot of the correlations between the P-values and fold changes (FD) for the metabolite signals in PANC-1 and H6c7 cells. (i) Volcano plot of the correlations between the P-values and fold changes (FD) for the metabolite signals in CFPAC-1 and H6c7 cells. (j) Total ion chromatogram (TIC),

(k) Distributed stochastic neighbor embedding (t-SNE) analysis of PANC-1, CFPAC-1, H6c7 and mixed cell suspension composed of PANC-1, CFPAC-1 and H6c7.

### 3.3.4 Deregulated ACLY Levels in PDAC

In order to investigate why lipid metabolism was abnormal in PDAC cells, we monitored the expression levels of ACLY which is the critical rate-limiting enzyme for lipid synthesis, in one human TCGA dataset consists of 167 normal and 179 PDAC patients.<sup>137</sup> The mRNA level of ACLY increased around 1.4 fold in PDAC (Figure 3.5a). We further confirmed the upregulated ACLY mRNA levels in PDAC cells by qPCR (Figure 3.5b). Since ACLY is one of the critical enzymes for acetyl-CoA and lipid acids synthesis, we also analyzed the acetyl-CoA and lipid metabolism biological pathways in the same TCGA dataset by Gene set Enrichment Analysis (GSEA). Interestingly, we found that the genes involved in the acetyl-CoA metabolic process and lipid homeostasis were enriched in human PDAC samples (Figures S3.14a and b). Combined with our in vitro data (Figure 3.4), we conclude that the ACLY levels and lipid metabolism is deregulated in human PDAC. Recent studies revealed that PI3K-AKT and mTORC1 signaling pathways control the level of ACLY.<sup>135,138</sup> We thus hypothesized that the upregulated ACLY in PDAC cells may due to the deregulated PI3K-AKT and mTORC1 pathways. To this end, we monitored the protein levels of the key members of both signalling pathways including: activated form of AKT (phosphorlation of AKT at ser473 site), total AKT, activated p70 S6K (phosphorlation of p70 S6K at T389 site) and total p70 S6K in PDAC and H6C7 cells by immunoblotting. Indeed, we found both signalling pathways are activated in PDAC cells evidenced by the upregulation of phos-AKT(Ser473)/total AKT and phos-p70 S6K(T389)/total p70 S6K

levels compared to H6C7 cells (Figures 3.5c–e), indicating that the deregulated PI3K/AKT and mTORC1 pathways may contribute to the high levels of ACLY in PDAC cells.

**Figure 3.5.** Deregulated ACLY levels in PDAC. (a) Relative ACLY mRNA levels in human normal and PDAC pancreatic samples. Mean  $\pm$  SD (n=167 in normal and n=179 in PDAC). \*\*, p<0.01. (b) Relative ACLY mRNA levels in PANC-1, CFPAC-1 and H6c7 cells. Mean  $\pm$  SD (n=3). \*, p<0.05. (c) Immunoblot (IB) analysis of the total cell lysate derived from PANC-1, CFPAC-1 and H6c7 cells. GAPDH was used as protein loading control. (d-e) Bar plots represent of the quantification of IB described in (c). qPCR and Immunoblot analysis were performed at the cell population level.

### 3.3.5 ACLY Inhibition-Induced Lipid Redistribution Was Specifically Detected by the DBDI-MS Platform

Since the biological evidence demonstrates that ACLY is abundant in human PDAC samples, we investigated the effect of an ACLY

chemical inhibitor on pancreatic cancer cells using the DBDI-MS platform. As shown in Figures 3.6a-g and S3.15a-g, PC(32:1), PC(34:1) and PC(36:2) are the three predominant lipids in PANC-1 and CFPAC-1. When PANC-1 and CFPAC-1 were treated with gemcitabine or DMSO, the intensity of PC(36:2) is higher than the intensity of PC(32:1), and the intensity ratio of PC(32:1)/PC(36:2) ( $m/z$  732.55/786.60) is similar. However, when PANC-1 and CFPAC-1 were treated with SB-204990, the intensity of PC(36:2) became lower than intensity of PC(32:1), and the intensity ratio of PC(32:1)/PC(36:2) ( $m/z$  732.55/786.60) was increased. Figures 3.6f and S3.15f show that compared with PANC-1 and CFPAC-1 cells treated with DMSO, the contents of PC(32:1), PC(34:1) and PC(36:2) in the cells treated with different concentrations of gemcitabine did not change significantly, but the contents of PC(32:1), PC(34:1) and PC(36:2) in PANC-1 and CFPAC-1 treated with different concentration of SB-204990 were significantly reduced, when the concentration of SB-204990 increased, the contents of PC(32:1), PC(34:1) and PC(36:2) decreased. The t-SNE clustering results in Figures 3.6h and S3.15h show heterogeneity of PANC-1 and CFPAC-1 after different treatments can be observed. PANC-1 and CFPAC-1 treated with SB-204990 were separated more significantly than PANC-1 and CFPAC-1 treated with gemcitabine or DMSO.

**Figure 3.6.** PANC-1 with different treatments. (a) Representative mass spectrum of PANC-1 treated with DMSO. (b) Representative mass spectrum of PANC-1 treated with 25  $\mu\text{M}$  Gemcitabine. (c) Representative mass spectrum of PANC-1 treated with 50  $\mu\text{M}$  Gemcitabine. (d) Representative mass spectrum of PANC-1 treated with 100  $\mu\text{M}$  SB-204990. (e) Representative mass spectrum of PANC-1 treated with 200  $\mu\text{M}$  SB-204990. (f) Bar plots for the changes of lipid contents after different treatments. (g) Violin plots for comparing the intensity ratio of PC(32:1)/PC(36:2) (m/z 732.55/786.60) in PANC-1 with different treatments. (h) t-SNE analysis of PANC-1 with different treatments.

Thus, the above results show that the lipid metabolism in PDAC cells could be reversed by ACLY inhibition, which further supports

the notion that deregulated ACLY contributes to the abundance of lipids in PDAC cells. Moreover, the modifications induced by ACLY inhibition could be specifically detected by our sensitive single-cell DBDI-MS platform. Because DBDI-MS shows high sensitivity and high specificity at the level of cell lines, it has the potential to classify the cells in clinical cancer tissues, identify the characteristic metabolites of different cancer types, and distinguish cancer subtypes.

### **3.3.6 ACLY May Serve as a Novel Target for Established PDAC**

The above findings revealed by our new DBDI platform inspired us to explore whether targeting ACLY could be beneficial for PDAC therapy. As a primitive ACLY inhibitor, SB-204990 displays tumor-suppressive effects in multiple tumors both *in vitro* and *in vivo*.<sup>139</sup>

To this end, we first treated PANC-1 and CFPAC-1 cells with the ACLY inhibitor SB-204990 and found a dosage dependent suppression of cell viability by SB-204990 in PDAC cells (Figures 3.7a and d). Accordingly, after transfecting PDAC cells with siRNA targeting ACLY (Figures 3.7b and e), we also found a significant reduction of cell viability (Figures 3.7c and f). Thus both chemical inhibitors or genetic approaches targeting ACLY could reduce PDAC cell viability, suggesting that ACLY could be a promising target in established PDAC.

**Figure 3.7.** Chemical inhibition or siRNA approach targeting ACLY repress PDAC cell viability at the population level. (a,d) Relative cell viability detected by MTT assay in PANC-1 and CFPAC-1 cells treated with indicated concentration of SB-204990 and DMSO for 48 hours. Mean  $\pm$  SD (n=4-8). (b,e) Relative ACLY mRNA expression in PANC-1 and CFPAC-1 cells transfected with si-control or si-Acly oligos. Mean  $\pm$  SD (n=3-4). \*\*,  $p < 0.01$ , unpaired t-test. (e,f) Relative cell viability detected by MTT assay in PANC-1 and CFPAC-1 cells transfected with si-control or si-Acly oligos for 72 hours. Mean  $\pm$  SD (n=6). \*\*,  $p < 0.01$ , unpaired t-test.

### 3.4 Conclusions

In conclusion, a high-throughput, label-free and sensitive DBDI-MS platform was developed for the analysis of single-cell metabolites, which achieved a throughput of approximately 38 cells per minute. The DBDI-MS platform is able to discriminate different cell types successfully based on their cellular metabolites. Compared with bulk cell analysis, our single-cell DBDI-MS platform can separate different cells from mixed cell suspensions according to its characteristic single-cell metabolite profile, and classify each type of

cell into a specific group, which may help detect lipid metabolism in clinical cancer tissues.

Since the DBDI-MS platform found that abnormal lipid metabolism occurs in pancreatic cancer cells, a series of biological methods were used to analyze the expression levels of ACLY and the activation of related biological pathways in the TCGA dataset and PDAC cells. We indeed found the deregulated ACLY, acetyl-CoA synthesis and lipid homeostasis pathways in PDAC. We further identified deregulated PI3K/AKT and mTORC1 pathways may promote the ACLY expression in PDAC.

By treating PDAC cells with different dosages of specific ACLY inhibitor, the redistribution of lipids in PDAC cells was observed by the DBDI-MS platform. Further biological experiments also demonstrated that both ACLY inhibitor or genetic approach that targeting ACLY could repress cell viability of PDAC cells. These results prove the high sensitivity of our DBDI-MS platform and also confirmed that ACLY indeed contributes to the lipid metabolism in PDAC cells, indicating ACLY may serve as a novel therapeutic target in PDAC.

Thus, our DBDI-MS platform may have the potential to serve as a new generation of mass cytometry and contribute to biological and clinical research.

## **3.5 Supporting information**

### **3.5.1 The specific configuration and operation details of DBDI mass cytometry platform**

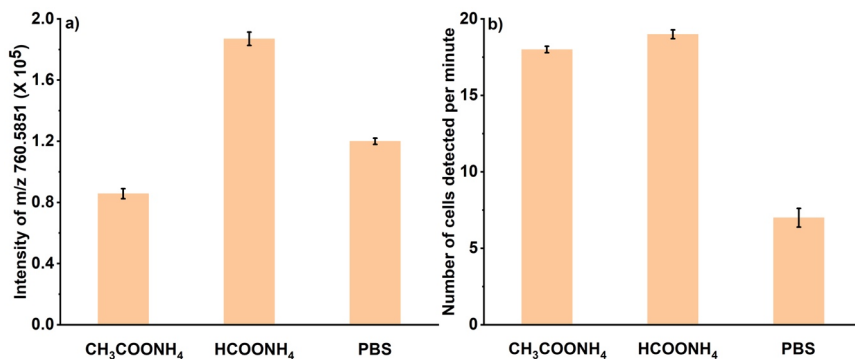

**Figure S3.1.** The specific configuration and operation details of DBDI mass cytometry platform, including: cell introduction system, a DBDI source, and an LTQ Orbitrap.

### 3.5.2 Optimization of experimental conditions for single-cell analysis

#### 3.5.2.1 The effect of the solvent for cell suspensions on single-cell analysis

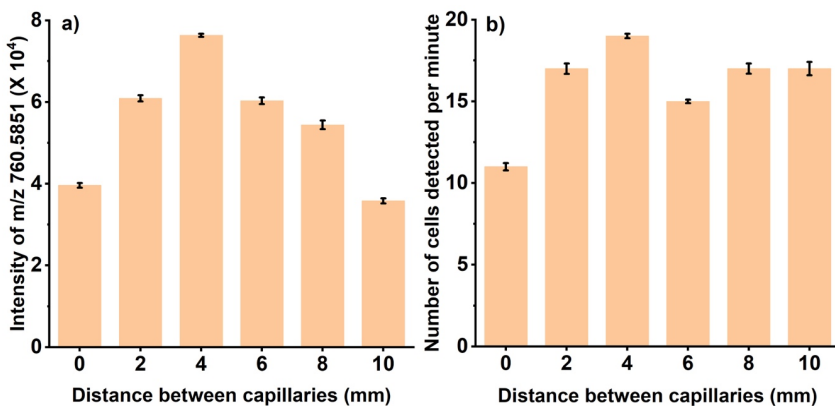

In order to maintain the structure of cells during the cell introduction process, the cells should be kept in an isotonic saline solution of neutral pH. As can be seen from Figure S3.2, different solvents had different effects on the intensity of cell metabolites and the number of cells detected per minute. Since the detected PC (34:1) had the highest intensity when the cells are in ammonium formate solution, and the number of cells detected per minute was also more than that detected in PBS and ammonium acetate, ammonium formate was thus selected as the solvent remain cell activity and integrity during further experiments.

**Figure S3.2.** The effect of the solvent for cell suspensions on single cell analysis (PANC-1 cell suspension was chosen as the example). (a) Extraction efficiency of PC (34:1), (b) number of cells detected per minute.

### 3.5.2.2 Effect of the distance of inner capillary and intermediate capillary on single-cell analysis.

The distance between inner capillary and intermediate capillary, which represent the interaction time between extract fluid (MeOH) and cells, can determine the extraction efficiency of metabolites in cells. As shown in Figure S3.3, when the distance between inner capillary and intermediate capillary was 4 mm, detected PC (34:1) had the highest intensity, and the number of cells detected per minute was also the most, 4 mm was thus selected as the optimal distance during further experiments.

**Figure S3.3.** The effect of the distance of inner capillary and intermediate capillary on single-cell analysis (PANC-1 cell suspension was chosen as the example). (a) Extraction efficiency of PC (34:1), (b) number of cells detected per minute.

### 3.5.2.3 Effect of the voltage of DBDI on single-cell analysis.

In brief, the PANC-1 cell suspension (at a flow rate of 1  $\mu\text{L}/\text{min}$ ) and MeOH (at a flow rate of 11  $\mu\text{L}/\text{min}$ ) were introduced into the DBDI source via the cell introduction system. As shown in Figure S3.4, when the DBDI voltage was 0 kV, there were no obvious pulse peak signals in TIC (Figure S3.4a) and EIC (Figure S3.4b). When the DBDI voltage is between 2.2 kV and 2.8 kV, the pulse peak signals appeared in both TIC (Figure S3.4a) and EIC (Figure S3.4b). As mentioned in the main text, this is because only when the DBDI was on, the compounds in the cells could be ionized. A voltage of 2.6 kV was chosen for further experiments. Interestingly, it can be seen that when the voltage was increased to between 3 kV and 3.5 kV, the pulse peak signals can still be observed from the TIC (Figure S3.4a), but the number of pulse peak signals in EIC decreased and the intensity of pulse peak signals in EIC became very low as well, which was probably due to the fact that although the DBDI source has been considered a soft ionization source, when the voltage increased above 3kV in this study, the lipid peaks were fragmented.

**Figure S3.4.** Effect of the voltage of DBDI on single-cell signal (PANC-1 cell suspension was chosen as the example). (a) Total ion chromatogram (TIC), (b) extracted ion chromatogram (EIC) of  $m/z$  760.5851.

### 3.5.2.4 Effect of the composition and flow rate of lysis/extraction fluid on single cell analysis.

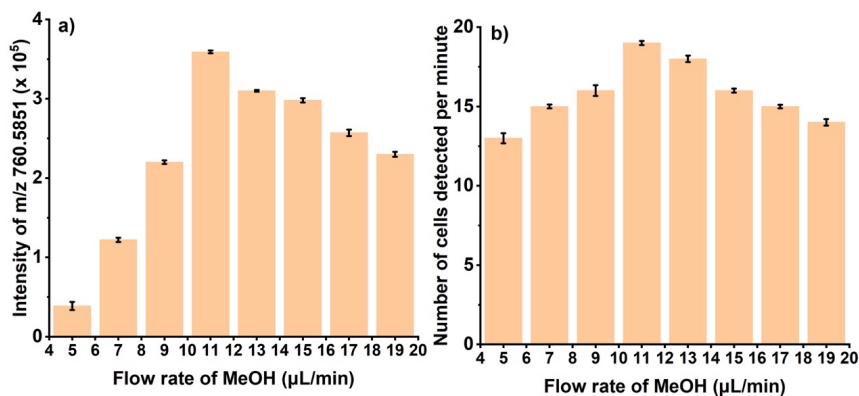

A suitable lysis/extraction fluid can help lyse cells and increase the coverage and signal intensity of the extracted metabolites. MeOH, EtOH, MeOH: H<sub>2</sub>O = 1:1 and EtOH: H<sub>2</sub>O = 1:1 were investigated in this work. As shown in Figure S3.5, the detected PC (34:1) had the highest intensity when pure MeOH was chose as the lysis/extraction fluid, and the number of cells detected per minute was also more than that detected in other lysis/extraction fluid, so MeOH was selected as the lysis/extraction fluid for further experiments.

The flow rate of MeOH has been optimized (Figure S3.6). As the flow rate was 11  $\mu$ L/min, the signal of PC (34:1) and the number of

detected cells were higher than other flow rates, so the flow rate of MeOH was set to 11  $\mu\text{L}/\text{min}$  during the entire experiment.

**Figure S3.5.** The effect of lysis/extraction fluid on single-cell analysis (PANC-1 cell suspension was chosen as the example). (a) Extraction efficiency of PC (34:1), (b) number of cells detected per minute.

**Figure S3.6.** The effect of the flow rate of MeOH on single-cell analysis (PANC-1 cell suspension was chosen as the example). (a) Extraction efficiency of PC (34:1), (b) number of cells detected per minute.

### 3.5.3 Feasibility of single cell DBDI-MS

To further evaluate the performance of DBDI-MS, analysis of different cell suspensions was carried out, including PANC-1 cells ( $3 \times 10^4$  cells/mL), CFPAC-1 cells ( $3 \times 10^4$  cells/mL) and H6c7 cells ( $3 \times 10^4$  cells/mL). The cell suspension was introduced into the DBDI source at a flow rate of 1  $\mu$ L/min under a continuous low-speed shaking by a vortex, which prevents the cells from depositing to the bottom of the vial, and make the suspensions homogenous and monodisperse. As can be seen from Figures S3.7a–c, Figures S3.8a–c and Figures S3.9a–c, the frequency and position of the m/z 760.5851 and m/z 732.5538 peaks matched with the frequency and position of the TIC, and the peak signals did not overlap with each other. Obvious lipid signals could be observed in the mass spectrum corresponding to the peaks (Figure S3.7e, Figure S3.8e and Figure S3.9e), but no lipid signals could be observed in the mass spectrum corresponding to the EIC between two peaks (Figure S3.7d, Figure S3.8d and Figure S3.9d). At a concentration of  $3 \times 10^4$  cells/mL, more than 500 cells were detected in 18 minutes, and at a concentration of  $2 \times 10^4$  cells/mL, more than 300 cells were detected in 18 minutes.

**Figure S3.7.** PANC-1 suspension analyzed by DBDI-MS. (a) Total ion chromatogram (TIC), (b) extracted ion chromatogram (EIC) of  $m/z$  760.5851, (c) EIC of  $m/z$  732.5538, (d) mass spectrum of blank, and (e) mass spectrum of PANC-1. The asterisk (\*) indicates electronic noise in the spectra.

Since the time available for analyzing a single cell was very limited, it was difficult to perform tandem MS for better characterization of the metabolites in a single cell. As shown in Figure S3.10, several lipids (SM(d34:1), PC(O-32:1), PC(32:1), PC(33:1), PC(34:1), PC(36:2)) in a population of PANC-1 cells were selected for tandem-MS analysis.

# Hybrid Ionization Source Combining Nanoelectrospray and Dielectric Barrier Discharge Ionization for the Simultaneous Detection of Polar and Nonpolar Compounds in Single Cells

This Chapter is adapted from: Qinlei Liu, Jiayi Lan, Ri Wu, Alina Begley, Wenjie Ge, and Renato Zenobi. *Anal. Chem.* **2022**, *94*, 2873-2881

Single-cell metabolomics is expected to deliver fast and dynamic information on cell function; therefore, it requires rapid analysis of a wide variety of very small quantities of metabolites in living cells. In this work, a hybrid ionization source that combines nanoelectrospray ionization (nanoESI) and dielectric barrier discharge ionization (DBDI) is proposed for single-cell analysis. A capillary with a 1  $\mu\text{m}$  i.d. tip was inserted into cells for sampling and then directly used as the nanoESI source for ionization of polar metabolites. In addition, a DBDI source was employed as a post-ionization source to improve the ionization of apolar metabolites in cells that are not easily ionized by ESI. By increasing the voltage of the DBDI source from 0 to 3.2 kV, the classes of detected metabolites can be shifted from mostly polar to both polar and apolar to mainly apolar. Plant cells (onion) and human cells (PANC-1) were

investigated in this study. After optimization, 50 compounds in onion cells and 40 compounds in PANC-1 cells were observed in ESI mode (3.5 kV) and an additional 49 compounds in onion cells and 73 compounds in PANC-1 cells were detected in ESI (3.5 kV)-DBDI (2.6 kV) hybrid mode. This hybrid ionization source improves the coverage, ionization efficiency, and limit of detection of metabolites with different polarities and could potentially contribute to the fast-growing field of single-cell metabolomics.

## 4.1 Introduction

Single-cell metabolic analysis provides useful information about cellular heterogeneity.<sup>33,140-141</sup> However, single-cell metabolomics is very challenging due to the low abundance and diverse structure of intracellular metabolites.

Mass spectrometry is a label-free analytical technique with high sensitivity, good selectivity, and fast response. It can simultaneously detect multiple low-molecular-weight metabolites in a cell and has been widely used for single-cell metabolomics.<sup>142-144</sup> The ionization method is crucial as it determines the coverage and limit of detection (LOD) of the metabolome. Mass spectrometry-based single-cell metabolomics mainly relies on secondary ion mass spectrometry (SIMS),<sup>26,33,145</sup> matrix-assisted laser desorption/ionization mass spectrometry (MALDI-MS),<sup>25,63</sup> and nanoelectrospray ionization mass spectrometry (nanoESI-MS).<sup>141,146</sup> SIMS has a high spatial resolution and can be used for subcellular analysis, but many fragments are usually generated during the ionization process. Although the spatial resolution of MALDI is far less than that of SIMS, MALDI is a soft ionization source that can detect many types of compounds with relatively high sensitivity. MALDI and SIMS have many applications in the area of single-cell imaging.<sup>145,147-148</sup> ESI-

based methods can be used for sampling and ionization of metabolites in living cells. Pioneering work in this area has been done by Masujima and co-workers.<sup>149-151</sup> They developed a “live single-cell MS” (LSC-MS) method and applied it to analyze metabolites in mouse embryonic fibroblasts cells,<sup>151</sup> human-derived circulating tumor cells (CTCs),<sup>149</sup> and plant cells.<sup>150</sup> Vertes and co-workers have demonstrated the efficient use of capillary microsampling combined with ESI and ion mobility separation (IMS) followed by MS for the analysis of single plant and animal cells.<sup>152-154</sup> Single-cell metabolite analysis by laser ablation ESI (LAESI) MS was also practiced by the same group,<sup>37,155</sup> and recently, they used it for single-cell high-throughput analysis.<sup>156</sup> Nemes and co-workers combined capillary electrophoresis (CE) and ESI-MS for single-cell analysis.<sup>157-159</sup> More recently, they enabled *in vivo* single-cell proteomics and metabolomics in South African clawed frog embryos *via* CE-ESI-MS.<sup>160</sup> Both of these groups used probe sampling and ESI ionization methods to study single cells. Each single-cell ionization method has its own advantages. For example, nanoESI is suitable for the ionization of polar metabolites, but it is less suitable for ionizing nonpolar metabolites due to its ionization mechanism.

We reasoned that different ionization methods can complement each other, which should be beneficial for the study of single-cell metabolomics. For example, dielectric barrier discharge ionization (DBDI) source is a sensitive, efficient, and cheap low-temperature plasma source, which is based on completely different ionization processes than ESI.<sup>94,98</sup> The plasma contains many reactive species, including electrons, ions, neutral atoms, excited states, radicals, and photons.<sup>161</sup> Reactive species in the plasma determine the ionization reactions and product ions.<sup>94,101,162</sup> Some reactive species (e.g.,  $N_2^{+*}$ ,  $O_2^{+*}$ ,  $N_2^*$ ) will lead to charging of nonpolar compounds through charge transfer, electron impact, or Penning ionization processes, while other reactive species (e.g.,  $(H_2O)_nH^+$ ) ionize polar compounds

*via* protonation. The applied voltage is a crucial parameter that influences the ionization efficiency and selectivity of the generated product ions. By increasing the plasma voltage, the energy and the number of electrons will increase.<sup>95</sup> A high applied voltages will thus increase the ionization efficiency.<sup>163</sup> In addition, DBDI can be operated with dopants to boost the ion yield of specific analytes.<sup>96</sup> Our group has developed a small, soft, and practical DBDI source with high ion transmission efficiency and has used it for single-cell metabolism analysis.<sup>34</sup> We have proven that DBDI-MS can detect multiple metabolites at the single-cell level and distinguish different cell types based on the information on detected metabolites.

Possible strategies to improve the ionization efficiency of nonpolar metabolites and expand the detection range of metabolites in single cells are to develop alternative ionization sources, post-ionization sources, or versatile hybrid ionization sources for single-cell metabolomics. Hybrid ionization sources have been used in the past, although only on the bulk level, never in the context of the analysis of nonpolar metabolites in single cells. For example, Shiea and co-workers introduced a combination of ESI with atmospheric pressure chemical ionization to post-ionize neutrals produced by laser desorption and thermal desorption. Both polar and nonpolar analytes were observed.<sup>164</sup> Another example is the use of matrix-assisted laser desorption electrospray ionization (MALDESI) for imaging applications, which was pioneered by Muddiman and co-workers.<sup>165-166</sup> They combined the benefits of MALDI and ESI post-ionization to increase the ion yield. The Franzke group also reported that DBDI can increase the signal intensity of lysine that has been ionized by ESI.<sup>167</sup> The general concept is to use a post-ionization scheme to boost the ion yield, and we propose that it would also be advantageous to ionize nonpolar metabolites and metabolites that exhibit low ionization yield. Therefore, we hypothesized that

combining ESI and DBDI will enlarge the range of metabolites that can be covered and lower the LOD, which is crucial for single-cell metabolomics.

In this study, we introduce a hybrid nanoESI-DBDI source for single-cell analysis, which has two modes: an “ESI mode” and a “hybrid mode” to detect intracellular metabolites with different polarities. As a proof of principle, a glass capillary with a tip diameter of 1  $\mu\text{m}$  was inserted into a cell for sucking in cell contents (Figure 4.1a), and then the cellular metabolites were ionized by the hybrid nanoESI-DBDI source (Figure 4.1b), where the nanoESI primarily ionizes polar metabolites, followed by a DBDI source as a post-ionization source to ionize less polar, nonpolar metabolites and metabolites with low ESI ionization yield. We were able to demonstrate the detection of metabolites from single plant and animal cells. This hybrid source improved the coverage of metabolites of different polarities from 50 metabolites (ESI mode) to 86 metabolites (hybrid mode) in onion cells, and from 40 metabolites (ESI mode) to 111 metabolites (hybrid mode) in PANC-1 cells.

**Figure 4.1.** (a) Single cell sampling process. (b) Photo of the nanoESI-DBDI ionization source.

## 4.2 Experimental Section

### 4.2.1 Chemicals

Methanol, acetonitrile (ACN), and chlorobenzene were purchased from Sigma-Aldrich Chemie GmbH (Buchs, Switzerland). Testosterone, l-valine, anthracene, fluoranthene, and *N,N*-dimethylformamide (DMF) were purchased from Fluka Chemie GmbH (Buchs, Switzerland). l-Threonine was purchased from AppliChem GmbH (Darmstadt, Germany). l-Cysteine was purchased from abcr GmbH (Karlsruhe, Germany). 08:0 PC and 12:0 PC (DLPC) were purchased from Avanti Polar Lipids (Alabaster). Yellow onions (*Allium cepa*) were purchased from a local supermarket in Zurich. Phosphate-buffered saline (PBS) was purchased from Thermo Fisher Scientific (Buchs, Switzerland). PANC-1 cells were purchased from American Type Culture Collection (ATCC).

### 4.2.2 Sample Preparation

Standard solutions of L-threonine, L-valine, L-cysteine, testosterone, 08:0 PC, 12:0 PC (DLPC), anthracene, and fluoranthene were prepared at a concentration of 10 ppm in MeOH/water (1:1), ACN/DMF (1:1), and chlorobenzene/DMF (1:1) separately. A mixture of the eight compounds was prepared at a concentration of 10 ppm in MeOH/water (1:1).

### 4.2.3 Cell Culture and Single-Cell Sampling

The epidermal cell layer of yellow onion bulbs was freshly peeled and placed on a glass slide, which was then placed on the platform of an inverted microscope (Nikon Eclipse Ti Light Microscope). A micropipette puller (Sutter Instrument, Novato) was used to fabricate capillaries with a 1  $\mu\text{m}$  tip. Next, the capillary was inserted into a capillary holder installed on a home-built manipulator. By adjusting the angle and distance between the tip of the capillary and

the cell, the capillary was carefully inserted into the cell. The sampling process was observed by optical microscopy (as shown in Figure 4.1a). Around 30% of the cytoplasmatic cell content was extracted by applying a negative pressure applied by the syringe on the back of the capillary holder. After the cell sampling, the tip of the pulled capillary was backfilled with 2  $\mu$ L of an assistant solvent.

PANC-1 cells were grown in Dulbecco's modified Eagle's medium (DMEM) with 10% (v/v) fetal bovine serum and 1% penicillin-streptomycin (P/S) at 37 °C in a humidified incubator (Thermo Fisher Scientific) with 5% CO<sub>2</sub>. Before single-cell sampling, the dish was washed twice with PBS and then washed twice with ammonia formate. The dish was then placed on the platform of an inverted microscope to select a target cell and observe the sampling process. The subsequent single PANC-1 cell sampling method was the same as for single onion cells. Sampling images of PANC-1 cell and onion cell are shown in Figure S4.1.

#### **4.2.4 Hybrid Ionization Source**

In this study, a hybrid ionization source (Figures 4.1b and S4.2) that combines nanoESI and DBDI was used to do single-cell analysis. A home-built nanoESI source was used to ionize polar metabolites in cells, followed by an active capillary plasma ionization source (based on a dielectric barrier discharge ionization) to ionize nonpolar metabolites in cells. The details about the home-built DBDI source can be found in a previous publication.<sup>98</sup> In brief, the DBDI has two electrodes (Figure S4.2), an inner electrode (grounded, stainless steel, ID: 0.6 mm and OD: 1.0 mm) and an outer electrode (high voltage, copper, ID: 1.55 mm, around a glass capillary). They are isolated by a glass capillary that acts as a dielectric barrier. When a high alternating current (AC) voltage is applied to the outer electrode, a plasma is ignited inside the capillary. The ignition voltage of DBDI is around 2.0 kVpp. The operating AC voltage of

DBDI in this work was 2.2–3.2 kVpp. The DBDI source was connected directly to the inlet capillary of the mass spectrometer to achieve almost 100% transmission efficiency of the ions formed.

#### **4.2.5 Mass Spectrometry**

An LTQ Orbitrap mass spectrometer (Thermo Fisher Scientific, San Jose) was used to acquire mass spectra in positive-ion mode and in full-scan mode at a resolution of 30 000 full width at half-maximum (FWHM) (at  $m/z$  400) with a mass tolerance specified to be <10 ppm. The mass-to-charge range was set to 50–1000, capillary voltage was 50 V, tube lens voltage was 120 V, capillary temperature was 320 °C, and AGC target =  $10^6$ . Mass spectra were acquired using 1 microscan and a maximum injection time of 50 ms.

#### **4.2.6 Data Analysis**

The Xcalibur software version 2.2 (Thermo Fisher Scientific, San Jose) was used to record the MS raw data generated from the LTQ Orbitrap. MS raw data (.raw) was converted to the mzXML format by the MSConvert software (ProteoWizard, v3.0)<sup>136</sup> and then imported into Matlab (R2019b version, MathWorks, Natick, MA) for preprocessing.

Metabolite assignments were carried out by comparing the observed mass with the theoretical mass in an onion metabolite database<sup>140</sup> and some other online databases, including Plant Metabolome Database (<http://scbt.sastra.edu/pmdb/>), Human Metabolome Database (<https://hmdb.ca/>), and the METLIN metabolite database (<https://metlin.scripps.edu/>).

## 4.3 Results and Discussion

### 4.3.1 Effect of the DBDI Source Voltage and the nanoESI-DBDI Ionization Mechanism

To evaluate the ability of nanoESI-DBDI-MS to analyze polar and nonpolar compounds, eight model compounds with different polarities were selected: L-threonine, L-valine, L-cysteine, testosterone, 08:0 PC, 12:0 PC (DLPC), anthracene, and fluoranthene.

We first investigated the effect of the DBDI operating voltage on the ionization efficiency of two compounds with different polarities. During the entire experiment, the nanoESI was turned on, using a voltage of 3.5 kV. As shown in Figure 4.2a, when the DBDI was turned off, L-threonine was ionized by the ESI source through proton transfer. When the voltage of DBDI was between 2.2 and 2.8 kV, the signal of L-threonine was higher than with only the ESI running. This may be because reactive species in the plasma ( $H^+$ ,  $H_3O^+$ , cluster ions, etc.) can increase the overall ion yield of L-threonine *via* proton transfer. However, the signal of L-threonine decreased with increasing DBDI voltage. Above 2.8 kV, the signal of L-threonine dropped significantly. We interpret this to be the result of L-threonine fragmentation (Figure S4.3), resulting in a decrease in its parent ion signal. On the contrary, anthracene could not be ionized when only the ESI was turned on (Figure 4.2b). When the DBDI was turned on, the signal of anthracene increased with increasing DBDI voltage. Anthracene may thus be mainly ionized *via* charge transfer, electron impact, or Penning ionization. As the DBDI voltage increases, the number of electrons in the plasma also increases, which helps to ionize anthracene, resulting in a signal enhancement. When the voltage of the DBDI source was 2.6 kV, the intensity of L-threonine was higher than when only the ESI was turned on, and the signal of anthracene was also relatively stable. Therefore, 2.6 kV was selected as the DBDI operating voltage for subsequent experiments.

In general, by simply adjusting the DBDI voltage from low to high (0–3.2 kV), the ionization reaction in the hybrid nanoESI-DBDI source is switched from proton transfer to charge transfer, electron impact, and Penning ionization. In this way, nanoESI-DBDI-MS can not only detect polar compounds but also analyze nonpolar compounds.

**Figure 4.2.** Effect of the DBDI voltage on the intensity of (a) L-threonine and (b) anthracene. ESI voltage was set to 3.5 kV in both cases.

### 4.3.2 Effect of Assistant Solvents

The effect of different solvents on the ionization efficiency of the model compounds was also studied.<sup>96,168</sup> Three solvent mixtures with different polarities (MeOH/water = 1:1, ACN/DMF = 1:1, chlorobenzene/DMF = 1:1) were used to dissolve the samples investigated here. The effect of these three assistant solvents on the intensity of the eight model compounds is shown in Figure S4.4 and described in detail in Section S4.5.3 in the Supporting Information (SI). Since both polar compounds and nonpolar compounds have good ionization efficiencies when MeOH/water (1:1) was used as the

assistant solvent, MeOH/water (1:1) was selected as the solvent for subsequent experiments.

The mass spectra of the eight compounds dissolved in MeOH/water (1:1) are shown in Figure 4.3. In ESI mode, the product ions of three polar amino acids appeared as  $[M + H]^+$  (Figures 4.3a-c). In hybrid mode, the ionization efficiencies of all product ions increased. For the three lipids (Figures 4.3d-f), the observed product ions were  $[M + H]^+$  and  $[M + Na]^+$ . Turning on the DBDI increased the ionization efficiencies of all product ions. For the two nonpolar PAHs (Figures 4.3 g,h), no prominent product ions were observed in ESI-only mode. In hybrid mode,  $[M]^{+•}$  ions were the dominant product ions. Based on the above results, it can be seen that when the DBDI voltage was set to 2.6 kV, the protonated species ( $RH^+$ ) in the plasma could improve the ionization of polar compounds to produce protonated molecular ions. Moreover, radical cations in the plasma could also promote ionization of nonpolar compounds.

By analyzing a mixture containing eight polar and nonpolar compounds, the ability of the hybrid source to simultaneously detect mixtures was further evaluated. As shown in Figure 4.4, L-threonine, L-valine, L-cysteine, testosterone, 08:0 PC, and 12:0 PC (DLPC) could be ionized in ESI mode, and their product ions were  $[M + H]^+$ . No product ions from anthracene and fluoranthene were observed. In the "ESI + DBDI" mode, L-threonine, L-valine, L-cysteine, testosterone, 08:0 PC, 12:0 PC (DLPC), and anthracene were all detected. The product ion of anthracene was  $[M]^{+•}$ , the product ions of other compounds were also  $[M + H]^+$ , and the intensity of all of the product ions was significantly improved except for fluoranthene. Although no product ions from fluoranthene were observed in the mixture due to the ion-suppression effects among different product ions, fluoranthene can be ionized by ESI-DBDI alone. The signal-to-noise ratios (S/N) of the eight model compounds indeed improved

after turning on the DBDI. For example, the S/N of L-threonine increased  $\sim 3$  times.

**Figure 4.3.** Mass spectra of eight model compounds with different polarities ionized by ESI and ESI-DBDI (solvent MeOH/water = 1:1): (a) L-threonine, (b) L-valine, (c) L-cysteine, (d) testosterone, (e) 08:0 PC, (f) 12:0 PC (DLPC), (g) anthracene, and (h) fluoranthene (ESI voltage: 3.5 kV; DBDI voltage: 2.6 kV; the asterisk (\*) indicates electronic noise in the spectra).

**Figure 4.4.** Mass spectrum of a mixture of eight model compounds with different polarities: L-threonine, L-valine, L-cysteine, testosterone, 08:0 PC, 12:0 PC (DLPC), anthracene, and fluoranthene (ESI voltage: 3.5 kV; DBDI voltage: 2.6 kV; the pound sign (#) indicates ACN + MeOH clusters; the asterisk (\*) indicates electronic noise in the spectra).

### 4.3.3 Single-Cell Metabolite Analysis

We then applied the ESI-DBDI hybrid source to analyze metabolites in both single plant cells and animal cells, analyzing dozens of cells and measuring at least three replicates for each cell type to validate the reproducibility and robustness of our method.

We first chose onion cells as an application example because single-cell analysis of onion cells has been widely reported.<sup>37,140,169-170</sup> It is also relatively easy to do sampling on an onion cell. After microsampling, the onion cell metabolites were analyzed by ESI-DBDI-MS. In the positive-ion mode ( $m/z$  range between 50 and 1000), approximately 50 metabolites were detected in ESI mode in onion cells (Table S4.1). The observed product ions were mostly  $[M + H]^+$  and  $[M + Na]^+$ , which are commonly seen in ESI. Some other common in-source fragments like  $[M + H - H_2O]^+$  and  $[M + H - 2H_2O]^+$  were also observed.<sup>171</sup> When the DBDI was turned on (2.6–2.8 kV), approximately 86 metabolites were detected (Table S4.2), among which 49 metabolites were not observed in ESI-only mode. Most of them were nonpolar. Except for  $[M + H]^+$ ,  $[M + Na]^+$ ,  $[M + H - H_2O]^+$ , and  $[M + H - 2H_2O]^+$ ,  $[M]^{+•}$  ions were also formed in hybrid mode.

Among all ionized metabolites in the onion cell, three polar metabolites (threonine, glutamine, and serine) and three nonpolar metabolites (2,5-dimethylthiophene, 1-propenyl propyl disulfide, and 5-hydroxymethyl-2-furancarboxaldehyde) were chosen as markers to highlight the differences between the ESI mode and the hybrid mode in detail. As shown in Figure 4.5a, when only ESI was on, only polar metabolites (threonine, glutamine, and serine) were detected. When the DBDI voltage was between 2.2 and 2.4 kV, the signal of threonine did not change significantly, and the signals of glutamine and serine were slightly reduced. At the same time, less polar metabolites (2,5-dimethylthiophene and 1-propenyl propyl disulfide) could be observed, but no clear signal from 5-hydroxymethyl-2-furancarboxaldehyde was observed. When the DBDI voltage was between 2.6 and 2.8 kV, the signal of polar metabolites (threonine, glutamine, and serine) decreased somewhat, while the signals of less polar metabolites (2,5-dimethylthiophene, 1-propenyl propyl disulfide, and 5-

hydroxymethyl-2-furancarboxaldehyde) increased significantly. When the DBDI voltage was between 3 and 3.2 kV, the signal of polar compounds was significantly reduced. Especially for glutamine, almost no obvious signal remained, but the signal of nonpolar compounds was further improved. By comparing the mass spectra of an onion cell in ESI mode (Figure 4.5b) and in hybrid mode (Figure 4.5c), it can be seen that the mass spectral profiles are quite different. For example, in ESI mode (Figure 4.6a), abundant peaks were at  $m/z$  102.06 (assigned to threonine),  $m/z$  164.07 (*S*-propyl-L-cysteine),  $m/z$  175.12 (arginine), and  $m/z$  184.07 (phosphorylcholine), which are polar onion cell metabolites. When the DBDI voltage was switched on to 2.6 kV (Figure 4.6b), less polar metabolites such as 3-(methylthiomethylthio)-1-propene ( $m/z$  89.04), 2,5-dimethylthiophene ( $m/z$  113.04), and di-1-propenyl sulfide ( $m/z$  115.05) were also observed in addition to polar metabolites such as furfuryl acetate ( $m/z$  123.04), arginine ( $m/z$  175.12), and citrullin ( $m/z$  198.09).

We also investigated PANC-1 cells, as an example of a human cell, by ESI-DBDI-MS in this study. As shown in Table S4.3, there were around 40 metabolites observed in ESI mode. The observed product ions and in-source fragments included  $[M + H]^+$ ,  $[M + Na]^+$ ,  $[M + K]^+$ ,  $[M + H - H_2O]^+$ , and  $[M + H - 2H_2O]^+$ . Approximately 111 metabolites were detected (Table S4.4) in a single PANC-1 cell when the DBDI was turned on (2.6–2.8 kV), of which additional 71 metabolites were not observed in ESI-only mode.  $[M + H]^+$ ,  $[M + Na]^+$ ,  $[M + K]^+$ ,  $[M + H - H_2O]^+$ , and  $[M]^{2+}$  ions were the observed product ions in hybrid mode.

**Figure 4.5.** Metabolite analysis in a representative single ion cell. (a) total ion chromatogram (TIC) and extracted ion chromatograms (EICs) of six metabolites in ion cells in ESI/hybrid mode. (ESI was always on: 3.5 kV), (b) mass spectrum acquired in ESI (3.5 kV) mode, (c) mass spectrum acquired in ESI (3.5 kV)-DBDI (2.6 kV) hybrid mode.

**Figure 4.6.** Metabolite analysis in a representative single PANC-1 cell. (a) total ion chromatogram (TIC) and extracted ion chromatograms (EICs) of six metabolites in onion cells in ESI/hybrid mode. (ESI was always on: 3.5 kV), (b) mass spectrum acquired in ESI (3.5 kV) mode, (c) mass spectrum acquired in ESI (3.5 kV)-DBDI (2.6 kV) hybrid mode.

Three polar (leucine, lysine, and arginine) and three nonpolar metabolites (1-pyrroline, dimethylurea, and  $\alpha$ -methylstyrene) were selected as markers from all of the ionized compounds to show the difference between ESI mode and hybrid mode. As shown in Figure 4.6a, nonpolar metabolites (1-pyrroline, dimethylurea, and  $\alpha$ -methylstyrene) were not detectable in ESI-only mode. When the DBDI voltage was between 2.2 and 2.6 kV, nonpolar metabolites (1-pyrroline, dimethylurea, and  $\alpha$ -methylstyrene) were observed. At the same time, the signal of polar metabolites (leucine, lysine, and arginine) significantly increased. When the DBDI voltage was between 2.8 and 2.3 kV, the signal of polar metabolites (leucine, lysine, and arginine) was reduced, while the signals of nonpolar metabolites (1-pyrroline, dimethylurea, and  $\alpha$ -methylstyrene) increased slightly. When the DBDI voltage was 3.2 kV, the signals of polar compounds were almost nondetectable, while the signals of nonpolar compounds did not change obviously. The mass spectral profiles of a PANC-1 cell in ESI mode and hybrid mode are evidently different. In ESI mode (Figure 4.6b), abundant peaks were at  $m/z$  116.07 (assigned to proline),  $m/z$  132.08 (creatinine),  $m/z$  147.11 (lysine), and  $m/z$  154.08 (leucine), which are polar PANC-1 cell metabolites. When the DBDI voltage was switched on to 2.6 kV (Figure 4.6b), polar metabolites including 1-pyrroline ( $m/z$  70.06), pyridine ( $m/z$  80.05), etc., and nonpolar metabolites including proline ( $m/z$  116.07), threonine ( $m/z$  142.05), etc. were detected at the same time.

The above results further confirmed that by adjusting the DBDI voltage, the ESI-DBDI source can be switched to different modes. When the DBDI is turned off, the metabolites in the cells are mainly ionized by the ESI source through proton transfer. Due to the complex environment in the cells, matrix effects, and ion

suppression, the ion yield of less polar and nonpolar metabolites is reduced. Since DBDI is less affected by matrix effects and ion-suppression effect than ESI, and there are many reactive species in the plasma, turning on the DBDI increased the ion yield of less polar and nonpolar metabolites *via* a range of ionization reactions, including proton transfer, charge transfer, electron impact, and Penning ionization. For high-throughput single-cell analysis, on-line infusion of a cell suspension into the hybrid source presented here could be used<sup>34</sup> and an automatic voltage scan, similar to data-independent acquisition in liquid chromatography–mass spectrometry (LC–MS), could be helpful.

## **4.4 Conclusions**

In this study, a hybrid ESI + DBDI ionization source was developed for single-cell analysis. The ESI-DBDI source can be operated in ESI mode and hybrid mode. In ESI mode, polar metabolites are ionized well. In hybrid mode, nonpolar or less nonpolar metabolites exhibit good ionization efficiency. By gradually increasing the DBDI voltage from 0 to 3.2 kV, the classes of ionized metabolites in cells can be shifted from mostly polar, to both polar and apolar, to mainly apolar. This hybrid ESI + DBDI source apparently relies on multiple ionization mechanisms such as proton transfer, charge transfer, and Penning ionization. It can thereby improve the ionization efficiency of metabolites of different polarities, the limit of detection, and the coverage of metabolites, which may contribute to the development of metabolomics at the single-cell level.

## **4.5 Supporting information**

**Figure S4.2.** The configuration of ESI-DBDI hybrid source.

## 4.5.2 Effect of the voltage of DBDI source

**Figure S4.3.** Fragment ions mass spectrum of L-threonine. (ESI voltage: 3.5 kV, DBDI voltage: >2.8 kV)

## 4.5.3 Effect of assistant solvents

As shown in Figures S4.4a, b and c, the ionization efficiencies of the three polar amino acids (L-threonine, L-valine, L-cysteine) dissolved in MeOH/water (1:1) and ACN/DMF (1:1) were higher than that in chlorobenzene/DMF(1:1) in ESI mode and hybrid mode. Compared with the ESI mode, the ionization efficiencies of the three polar amino acids dissolved in MeOH/water (1:1), ACN/DMF (1:1) and chlorobenzene/DMF (1:1) were significantly improved in the hybrid mode. For the non-polar lipid testosterone (Figure S4.4d), when the assistant solvent was MeOH/water (1:1), [M+H]<sup>+</sup> and [M+Na]<sup>+</sup> could be observed in both ESI mode and hybrid mode, and [M+H]<sup>+</sup> were the predominant product ions. Compared with the ESI

mode, the intensity of  $[M+H]^+$  and  $[M+Na]^+$  increased after the DBDI source was turned on, and  $[M+H]^+$  were still the main product ions. When the assistant solvents were ACN/DMF (1:1) and chlorobenzene/DMF (1:1), no obvious product ions were detected in ESI mode and hybrid mode. For the polar lipids 08:0 PC and 12:0 PC (DLPC) (Figures S4.4e and f),  $[M+H]^+$  and  $[M+Na]^+$  could be observed in both ESI mode and hybrid mode,  $[M+H]^+$  were the dominant product ions when the assistant solvent was MeOH/water (1:1). After DBDI was turned on, the intensity of  $[M+H]^+$  and  $[M+Na]^+$  were significantly improved. When the assistant solvents were ACN/DMF (1:1) and chlorobenzene/DMF (1:1), although the ionization efficiencies of all product ions were lower than when the assistant solvent was MeOH/water (1:1), the ionization efficiencies of all product ions were improved when DBDI was turned on. We also measured two polycyclic aromatic hydrocarbons (PAHs) (anthracene and fluoranthene). Although they are hardly found in cells, they are non-polar and difficult to ionize, so they were used to evaluate the ability of ESI-DBDI to ionize non-polar compounds. It can be seen from Figures S4.4g and h that when only switched on ESI, the two PAHs dissolved in MeOH/water (1:1), ACN/DMF (1:1) and chlorobenzene/DMF (1:1) had no obvious signals. In hybrid mode, when the assistant solvent was chlorobenzene/DMF (1:1), the ionization efficiencies of anthracene and fluoranthene were higher than when the assistant solvent was MeOH, and  $[M]^{2+}$  was the main product ions. When the assistant solvent was ACN, there were no obvious signals. Based on the above results, both polar compounds and non-polar compounds have good ionization efficiencies when MeOH/water (1:1) was used as the assistant solvent, so MeOH/water (1:1) was selected as the assistant solvent for subsequent experiments.

**Figure S4.4.** Effect of assistant solvents (MeOH: water=1:1, ACN: DMF=1:1, Chlorobenzene: DMF=1:1) on the intensity of 8 compounds with different polarities. (a) L-threonine, (b) L-valine, (c) L-cysteine, (d) testosterone, (e) 08:0 PC, (f) 12:0 PC

(DLPC), (g) anthracene and (h) fluoranthene. (ESI voltage: 3.5 kV, DBDI voltage: 2.6 kV)

### Development of a 3D-Printed Ionization Source for Single-Cell Analysis

This chapter presents a method for manufacturing an ionization source that is specially adapted for mass spectrometry-based single-cell analysis using 3D printing technology. This all-in-one 3D-printed ESI source integrates the sample introduction, metabolite extraction and ionization into one device, simplifying the process of single-cell analysis and improving the reproducibility of the measurement. We successfully used it for high-throughput analysis of three types of cancer cells (around 17 cells/min), and used the t-SNE algorithm to distinguish different cell types based on selected features. When compared to other ionization sources, 3D-printed ionization sources have the advantages of low cost, fast fabrication time, and mass production.

#### 5.1. Introduction

The study of metabolic heterogeneity in cells is essential to understand the physiology and pathology of diseases.<sup>172-174</sup> In this context, it is of great interest to perform metabolomics at the single-cell level. However, analyzing metabolites in single cells is difficult due to the fast metabolic dynamics, the large diversity of the molecular structures, and the inability to label or amplify metabolites.<sup>1</sup>

In recent years, mass spectrometry has been widely used for single-cell metabolomics analysis because it is very sensitive, highly specific, and able to analyze multiple molecules

simultaneously.<sup>20,26,29,32,34-35,37,44,48,57,63,76,175</sup> The electrospray ionization (ESI) source is one of the most popular used ionization sources in single-cell mass spectrometry.<sup>20,37,44,48,57,175</sup> It is an atmospheric pressure ionization source that does not require a vacuum operating environment and can sample single cells in situ for analysis. For example, Masujima and colleagues pioneered this field by developing a "live single-cell MS" (live MS) method and using it to investigate subcellular metabolites in RBL-2H3 (rat leukemia cell line),<sup>24</sup> plant cells<sup>39,41</sup> and CTCs.<sup>38</sup> Yang and co-workers developed a single-probe-based nanoESI source to directly analyze metabolites in single HeLa cells.<sup>42</sup> Vertes and co-workers proposed *in-situ* analysis of individual cells by LAESI-MS at atmospheric pressure, and successfully analyzed metabolites plant cells.<sup>37</sup> Because hundreds or thousands of measurements are required in biology to produce statistically significant data, this places challenging demands on the throughput of single-cell mass spectrometry. Therefore, microfluidic methods have been coupled with nanoESI for single-cell analysis to enable high-throughput analysis and obtain biologically meaningful data.<sup>56-60</sup> For example, capillary microfluidics platform-based flow cytometry ESI-MS (CyESI-MS) technique<sup>57-58</sup> developed by Zhang group and organic mass cytometry combining nanoESI with microfluidic chips<sup>59</sup> proposed by Liu group have been used to achieve high-throughput single-cell analysis. Although these methods have achieved high-throughput single-cell analysis, the assembly of the cell introduction system and its assembly with the ESI source may be biased, which will affect the reproducibility and accuracy of results.

Here, we report on a versatile all-in-one three-dimensional (3D)-printed ESI source for single-cell analysis that simplifies the process and improves the reproducibility of single-cell analysis by integrating sample introduction, metabolite extraction, and

ionization of analytes into one unit (Figure 5.1). In this study, 3D printing provided sharable CAD data, good reproducibility, high accuracy, short manufacturing time and low printing cost for this 3D-printed ionization source. The capability of the 3D-printed ionization source was validated by successful analyses of three types of cancer cells. To the best of our knowledge, this is the first time 3D-printing technology has been used to design an ionization source for single-cell analysis.

## **5.2. Experimental Section**

### **5.2.1 Chemicals, Materials and cells**

Methanol (99.9%) and ammonium formate (>99.0%) were purchased from Sigma-Aldrich Chemie GmbH (Buchs, Switzerland). 0:8 PC and 0:12 PC were purchased from Avanti Polar Lipids (Birmingham, UK). Phosphate Buffer Saline (PBS) were purchased from Thermo Fisher Scientific (Buchs, Switzerland). Fused silica capillary tubes were purchased from Polymicro Technologies (BGB Analytik AG, Switzerland). HeLa, Panc 10.05 and AsPC-1 cells were purchased from ATCC.

### **5.2.2 Cell culture**

HeLa was maintained in DMEM medium supplied with 10% (v/v) fetal bovine serum and 1% Penicillin-Streptomycin (P/S). Panc 10.05 and AsPC-1 cells were maintained in RPMI-1640 medium supplemented with 10% (v/v) fetal bovine serum and 1% Penicillin-Streptomycin (P/S). The cells were cultured at 37°C in the humidified incubator (Thermo Fisher Scientific) with 5% CO<sub>2</sub>.

### **5.2.3 Preparation of Cell Suspensions**

Prior to the experiment, cells were trypsinized and centrifuged at 1000 rpm for 4 minutes to remove the medium, and then they were resuspended in 1xPBS. The cells were resuspended in 140 mM NH<sub>4</sub>COOH solution after undergoing a second centrifugation (1000 rpm, 4 minutes) to remove PBS.

### **5.2.4 Design and fabrication of the 3D-printed ionization source**

Autodesk Inventor Professional 2021 (California, USA) was used to design the 3D-printed ionization source, which was then printed using “VisiJet M2R-CL” material (3D Systems, California, USA) by a professional 3D printer (ProJet MJP 2500, 3D Systems, California, USA). The 3D-printed ionization source was cleaned with steam and isopropanol after printing, and dried in an oven for 24 hours before usage. The details of the design of the 3D-printed ionization can be found in the technical drawing shown in Figure 5.1a. In brief, the all-in-one 3D-printed ESI source consists of three channels, as shown in Figure 5.1a. The external channel (1 mm I.D.) was used for gas introduction. MeOH was introduced from the intermediate channel (300 μm I.D.) as an extraction solution. A fused silica capillary (193 μm O.D., 75 μm I.D.) was inserted through the internal channel (200 μm I.D.) of the 3D-printed ionization source to deliver cell suspensions. Figure 5.1b shows a photograph of the 3D-printed ionization source.

**Figure 5.1.** Schematic diagram (Figure 5.1a) and photograph (Figure 5.1b) of the 3D-printed ionization source. Cells are introduced, lysed by a coaxial flow of methanol, and N<sub>2</sub> gas serves as a sheath gas to help produce the spray. (When the MeOH flow rate was 10 µL/min and the distance between the inner capillary and the intermediate channel was 4 mm, the highest signal intensity of PC (34:1) was detected, and the highest number of cells per minute was detected, so these conditions were chosen for further experiments.)

### 5.2.5 Procedure for single-cell analysis

Before cell introduction, the intermediate channel was carefully washed with MeOH, and the inner capillary was thoroughly rinsed with a 140 mM NH<sub>4</sub>COOH aqueous solution until the background total ion chromatogram (TIC) remained stable. The freshly prepared cell suspension was injected into the inner capillary at a flow rate of 1 µL/min, while MeOH was introduced into the intermediate channel at a flow rate of 10 µL/min. A DC voltage of 5.0 kV was applied to the MeOH through an electrode, creating a stable electrospray at the tip of the intermediate channel. As shown in Figure 5.1a, the outlet end of the intermediate channel was 4 mm longer than the outlet end of the inner capillary. When the cell suspension exits the inner capillary and comes into contact with MeOH in the intermediate channel, the cells are lysed and metabolites in the cells are extracted into MeOH and nebulized into the mass spectrometer with the assistance of a flow of nitrogen sheath gas in the external channel. All channels were

flushed with MeOH for 10 minutes at a flow rate of 7 L/min following each measurement.

### **5.2.6 Mass Spectrometry**

Mass spectra were acquired in positive ion mode, with an LTQ Orbitrap mass spectrometer (Thermo Fischer Scientific, San Jose, U.S.A.), in full scan mode at a resolution of 30,000 FWHM (at  $m/z$  400) with a mass tolerance specified to be  $< 10$  ppm. The mass-to-charge range was set to 100–1000, the capillary voltage was 50 V, the tube lens voltage was 120 V, the capillary temperature was 320°C, and the AGC target value was  $10^6$ . Mass spectra were acquired using 1 microscan and a maximum injection time of 10 ms.

### **5.2.7 Data analysis**

Raw files were converted to mzML format by using the module MSConverter in the ProteoWizard (v3.0) software. After this, all analyses and graphs were made with the software R. The spectra were extracted and preprocessed with the MALDIQUANT package for R. This indicated normalization to the TIC, spectrum alignment, signal-to-noise filtering with a value of 3, removal of features present in less than 20% of samples and those with more than 20% of zero values. The markers PC (34:1) ( $m/z$  760.5894) and PC (32:1) ( $m/z$  732.5554) were chosen to detect single cells and extract all associated ion signals. Then the t-SNE algorithm was constructed with 388 features (perplexity value of 50 and 5000 iterations).

### 5.3. Results and Discussion

Before detecting cells, two phosphatidylcholine standards (0:8 PC and 0:12 PC) dissolved in MeOH were used to evaluate the viability of the 3D-printed ionization source. As shown in Figure 5.2, the ions of these two phosphatidylcholines appeared as  $[M + H]^+$  and  $[M + Na]^+$ , which are regularly observed in ESI.

**Figure 5.2.** Mass spectra of two lipids measured by the 3D-printed ion source, (a) 0:8 PC and (b) 0:12 PC (ESI voltage: 5 kV; the asterisk (\*) indicates electronic noise in the spectra.)

We then applied the 3D-printed ionization source for single-cell analysis of AsPC-1 cells. An AsPC-1 cell suspension ( $2 \times 10^4$  cells/mL) was introduced into the 3D-printed ionization source. The lipid PC (32:1) ( $m/z$  732.55), the main component of the cell membrane, was selected as a marker for cell lysate entering the mass spectrometer, and its signal pulses in the extracted ion chromatogram (EIC) matched those in the total ion chromatogram (TIC) (Figures 5.3a and b), and separate mass spectra of individual cells could be extracted from the signal pulses in the EIC (Figure 5.3c). As shown in Figures 5.3a and b, 17 cells on average were detected per minute, which is slightly lower than the theoretical number of 20 cells/min,

calculated from the cell diversity of the suspension and the flow rate, probably due to the cell introduction process that led to some cell loss and occasional inclusion of more than 1 cell.

**Figure 5.3.** Three types of cancer cells measured by the 3D-printed ionization source in positive mode. (a) TIC and (b) EIC of  $m/z$  732.5554 of an AsPC-1 cell suspension. (c) Typical AsPC-1 single-cell mass spectrum. (d) Typical Panc 10.05 single-cell mass spectrum. (e) Typical HeLa single-cell mass spectrum. (f) t-SNE analysis of AsPC-1, Panc 10.05 and HeLa cells, each point represents a cell, and clustering for each cell type can be observed. (AsPC-1 and Panc 10.05 are human pancreatic cancer cell lines, and HeLa is a human cervical cancer cell line.)

After validating the capability of 3D-printed ionization source for single-cell analysis, we used it to measure two more cancer cell types, Panc 10.05 cells and HeLa cells, to study cellular heterogeneity. The mass spectra of Panc 10.05 and HeLa cells are shown in Figures 5.3d and e. After data preprocessing, the t-SNA selected 388 features from these three cancer cell lines. We then used t-distributed stochastic neighbor embedding (t-SNE), an unsupervised nonlinear technique useful for data visualization. Based on the chemical profiles obtained after data treatment, three types of cancer cells are visualized by the t-SNE algorithm. (Figure 5.3f).

## 5.4. Conclusions

Overall, this work is the first to use a 3D-printed ionization source for single-cell analysis. This all-in-one 3D-printed ESI source was successfully applied to analyze three different types of cancer cells (AsPC-1, Panc 10.05 and HeLa) with a throughput of approximately 17 cells per minute. Based on the measured compounds, our method allows distinguishing different cancer cells. The development of 3D-printed ionization sources provides more possibilities for single-cell analysis.

### Conclusions & Outlook

Because even populations of clonal cells are heterogeneous, it is of great significance to develop analysis methods with single-cell sensitivity. Mass spectrometry is increasingly used for single-cell analysis, due to its high sensitivity, good selectivity, and ability to detect multiple compounds simultaneously. Single-cell mass spectrometry cannot be advanced further without the development of ionization sources, because any ionization source has its own advantages and limitations, and different methods can complement each other.

In this dissertation, home-built ambient ionization sources, including a DBDI source, a hybrid ESI-DBDI source and a 3D-printed ionization source, were developed to investigate single-cell metabolomics.

Firstly, a high-throughput (38 cells/min), label-free and sensitive DBDI-MS platform was developed for the analysis of single-cell metabolites. The DBDI-MS platform is able to discriminate different cell types (HEK-293T, PANC-1, CFPAC-1, H6c7, HeLa, and iBAs) successfully, based on the presence of different cellular metabolites. A key innovation of this work is that mass spectrometry was used to provide novel insights into abnormal lipid metabolism in established PDAC. We propose that ACLY could be a potential target for treating established PDAC. A variety of biological methods were used to investigate the expression levels of ACLY and the activation of related biological pathways in the TCGA dataset and PDAC cells. The DBDI-MS platform observed the redistribution of lipids in PDAC cells after treating them with different doses of a specific ACLY inhibitor. Further biological experiments revealed that both ACLY inhibitors

and genetic approaches targeting ACLY could suppress PDAC cell viability. These findings demonstrate the high sensitivity of our DBDI-MS platform and confirm that ACLY does indeed govern lipid metabolism in PDAC cells, implying that ACLY could be a novel therapeutic target in PDAC. As a result, our DBDI-MS platform has the potential to become useful for mass cytometry, thereby contributing to biological and clinical research.

Next, we reported a hybrid ionization source that combines ESI and DBDI to improve analyte coverage (mainly targeting non-polar compounds). This hybrid ESI + DBDI source apparently relies on several ionization processes, including Penning ionization, charge transfer, and proton transfer. In this work, the metabolites in human (PANC-1) and plant cells (onion) were investigated. After optimization, 40 compounds in PANC-1 cells and 50 compounds in onion cells were detected in ESI only mode (3.5 kV). In ESI (3.5 kV)-DBDI (2.6 kV) hybrid mode, additional 73 compounds in PANC-1 cells and an additional 49 compounds in onion cells were measured. With its improved coverage, ionization efficiency, and limit of detection of metabolites with various polarities, this hybrid ionization source may help to accelerate the development of single-cell metabolomics.

Finally, we proposed a 3D-printed ionization source for single-cell analysis. Three types of cancer cells (AsPC-1, Panc 10.05, and HeLa) were successfully measured using the ionization source at a throughput of about 17 cells per minute. Our technique enables cell type discrimination of various cancer cells based on the detected metabolites. This ionization source is cheaper, more reproducible, and more easily manufactured as compared to other ionization sources. The development of 3D-printed ionization sources also opens up new avenues for single-cell analysis.

Despite the progress made in mass spectrometry-based single-cell analysis, there is still some space for improvement:

### **(1) Sampling methods.**

Most current single-cell mass spectrometry techniques are destructive, which makes it difficult to monitor and measure intracellular metabolites in real time during cell proliferation or drug treatment. Therefore, it is necessary to develop *in-situ* non-destructive single-cell sampling methods that work efficiently and high throughput, without interfering with the normal metabolic processes of cells. For example, Nemes and co-workers employed *in-situ* microprobe sampling for developing *Xenopus laevis* embryos. After sampling and measurement, they tested the embryos' viability and found that they can still develop freely into visually normally behaving tadpoles.<sup>51</sup> However, this sampling method is still on the slow side in terms of throughput.

The efficiency of single-cell analysis can be increased by developing single-cell automatic sampling devices, which can save time for sampling and effort of the experimenter. The sample throughput of single-cell mass spectrometry can be improved by combining cell sorting techniques such as flow cytometry and inkjet cell printing, or microfluidic chips with mass spectrometers. For example, Zhang and co-workers proposed a capillary microfluidics platform-based flow cytometry ESI-MS (CyESI-MS) technique to achieve high-throughput single-cell analysis (38 cells/min), cell type discrimination, and biomarker screening.<sup>57-58</sup> Liu and co-workers combined nanoESI with microfluidic chips to identify 100 metabolites and 6 protein biomarkers in single cancer cells with a high throughput of 40 cells/min, and they successfully distinguished different cell types based on the information of simultaneously detected proteins and metabolites.<sup>59</sup>

### **(2) Sensitivity and dynamic range of mass spectrometry.**

Since the intracellular chemical composition is very complex, the size of a cell is very small, and some intracellular metabolites are present only at the trace level, single-cell metabolomics is challenging. Therefore, it is important to improve the sensitivity and dynamic range of mass spectrometry to realize the detection of low-abundance metabolites in single cells. Improvements in instrument functionality and sample preparation steps will help to improve the overall sensitivity and dynamic range required for routine single-cell metabolomics analysis.

### **(3) Ionization methods.**

Each single-cell ionization method has its own advantages. For instance, although SIMS has a high spatial resolution and is suitable for subcellular analysis, the ionization process typically results in many fragments. Although the spatial resolution of MALDI is far less than that of SIMS, MALDI is a soft ionization method that can detect a wide range of compounds with relatively high sensitivity. However, MALDI needs a relatively complex sample preparation. NanoESI can be used for sampling and ionization of metabolites in living cells, and it is suitable for the ionization of polar metabolites, but it is less suitable for ionizing nonpolar metabolites due to its ionization mechanism. Since different ionization methods can complement each other, developing new ionization sources and hybrid sources should be beneficial for the study of single-cell metabolomics. For example, in this dissertation, we developed a DBDI source and a hybrid ionization source that combines ESI source and DBDI source to improve metabolites coverage in single cells. In addition, we fabricated and used a high-throughput ESI-based 3D-printed ionization source for single-cell metabolomics. This 3D-printed ionization source integrates the cell introduction system, metabolite extraction and ionization source into one unit, simplifying the process of single-cell analysis.

#### **(4) Multi-omics research.**

The range of biomolecules that can be detected in single cells is continuously expanding due to the improvement of the performance of single-cell analysis methods. The study of single-cell multi-omics has become increasingly popular. For example, Nemes and co-workers enabled *in vivo* single-cell proteomics and metabolomics in South African clawed frog embryos *via* CE-ESI-MS.<sup>160</sup> Future omics research will continue to go deeper, not only focusing on measurement issues but also penetrating into important cell biology-related issues. Mass spectrometry can be combined with multiple techniques to obtain more information, thus realizing the study of single-cell multi-omics.

#### **(5) Data analysis for single-cell metabolomics.**

The lack of well-established open-access data analysis platforms that are particularly suitable for single-cell metabolomics is a problem that prevents the widespread development of single-cell metabolomics. Each laboratory has to develop its own tools, which hinders collaboration and attempts to reproduce the results. This is made even more difficult by the variety of mass spectrometric methods used in single-cell metabolomics, and consequently, the file formats and kinds of data collected. Therefore, it is still work in progress for MS-based single-cell metabolomic research to design standardized and validated single-cell data analysis pipelines for metabolomics with the correct identification of noise sources.

In conclusion, single-cell metabolomics should be combined with information from single-cell proteomics, genomics, and transcriptomics to study metabolic pathways and principles based on the detection of metabolites, in order to be able to address and solve profound problems related to life sciences, human health and disease. We hope to have delivered some encouraging ideas for the development of single-cell mass spectrometry in this thesis.

## A. Mass Spectrometry Reveals High Levels of Hydrogen Peroxide in Pancreatic Cancer Cells

Reactive oxygen species (ROS) are critical for many cellular functions, and dysregulation of ROS involves the development of multiple types of tumors, including pancreatic cancer. However, ROS have been grouped into a single biochemical entity for a long time, and the specific roles of certain types of ROS in tumor cells (e.g., PDAC) have not been systematically investigated. In this work, a highly sensitive and accurate mass spectrometry-based method was applied to study genetically modified animals and human PDAC cells. The results show that the oncogenic *KRAS* mutation promotes the accumulation of hydrogen peroxide ( $\text{H}_2\text{O}_2$ ) rather than superoxide or hydroxyl radicals in pancreatic cancer cells. We further identified that the enriched  $\text{H}_2\text{O}_2$  modifies cellular metabolites and promotes the survival of pancreatic cancer cells. These findings highlight the specific roles of  $\text{H}_2\text{O}_2$  in pancreatic cancer development, which may provide new directions for pancreatic cancer therapy.

### 1. Introduction

Reactive oxygen species (ROS), in particular hydrogen peroxide ( $\text{H}_2\text{O}_2$ ), superoxide ( $\cdot\text{O}_2^-$ ) and hydroxyl radicals ( $\cdot\text{OH}$ ), play important roles in tissue homeostasis, cellular signaling, differentiation, and survival.<sup>1-2</sup> ROS dysregulation contributes to the

development of various diseases, including multiple types of cancer.<sup>2</sup> However, whether ROS can prevent or promote the development of cancer remains controversial. Cellular responses to ROS are complex and they usually reflect a complex integration of various ROS types and levels. Therefore, ROS have mostly been studied as a whole, which unavoidably renders the precise roles of various ROS in tumor cells unclear.<sup>3</sup> Early literature showed that ROS play a major role in translational regulation processes as well as metastasis in pancreatic ductal adenocarcinoma (PDAC), which is the most lethal solid tumor.<sup>3-5</sup> More recently, we have studied pancreatic cancer initiation as well as lipid metabolism taking advantage of the genetic animal models and single-cell mass spectrometry.<sup>6-7</sup> However, the specific roles of specific ROS in PDAC remain unclear, which necessitates the use of appropriate assay techniques to study the functions and levels of specific ROS in PDAC.

From the analytical point of view, the detection of ROS is not easy, due to the fact that most oxygen radicals are unstable, short-lived and can interfere with each other. Current methods used to detect ROS include fluorescent<sup>8</sup> and chemiluminescent assays,<sup>9-10</sup> chromatographic<sup>11</sup> and spectrophotometric methods,<sup>12-13</sup> electrochemical biosensors<sup>14-15</sup> as well as electron paramagnetic resonance (EPR).<sup>16</sup> Luminous detection probes are cell-permeable and can form stable adducts. However, these probes lack specificity and sensitivity to the target ROS.<sup>11</sup> In addition, the reaction process and products of chromatography methods are complex. Electrochemical biosensors require complicated preparation, and the types of proteins coated on the electrode surface are limited. EPR analysis is not suitable for detecting intracellular ROS.<sup>17</sup> Alternatively, mass spectrometry (MS) is a promising technique to detect different types of ROS rapidly, and with high selectivity, sensitivity and accuracy. MS has been coupled with liquid

chromatography (LC) to detect 2-hydroxyethidium (2OH-E<sup>+</sup>), the reaction product of O<sub>2</sub><sup>•-</sup> with the fluorescent probe hydroethidine (HE), and 7-hydroxycoumarin (COH), the reaction product of H<sub>2</sub>O<sub>2</sub> with the fluorescent probe coumarin boronic acid (CBA).<sup>18-21</sup> Furthermore, fluorescent probe-based methods usually induce the formation of several adducts that would absorb or emit light at similar wavelengths. MS can accurately detect the mass-to-charge (m/z) ratio of specific adducts, thereby avoiding such interferences. Here, a mass spectrometry-based method was established to specifically measure different types of ROS in PDAC cells. More specifically, we detected the product 2-hydroxyethidium (2OH-E<sup>+</sup>) formed from the reaction of hydroethidine (HE) with O<sub>2</sub><sup>•-</sup>, the product 2,3-DHBA formed from salicylic acid and •OH, and the product 7-hydroxycoumarin (COH) formed from coumarin-7-boronic acid (CBA) and H<sub>2</sub>O<sub>2</sub> by mass spectrometry (Figure S1).

Using mass spectrometry for direct infusion of cell lysates, we found that the level of H<sub>2</sub>O<sub>2</sub> instead of •O<sub>2</sub><sup>•-</sup> or •OH, was dysregulated in murine and human PDAC cells. By using genetic techniques, we also showed that the oncogenic KRAS mutation in PDAC cells not only promoted the production of H<sub>2</sub>O<sub>2</sub>, but also suppressed the catalase (*CAT*) gene expression, which is the specific enzyme that metabolizes H<sub>2</sub>O<sub>2</sub>. We further monitored the effect of high levels of H<sub>2</sub>O<sub>2</sub> on cellular metabolites and cell viability in PDAC cells.

## 2. Experimental Section

### 2.1 Chemicals, Materials and cells

Methanol (99.9%), ammonium formate (>99.0%), catalase, N-acetyl-L-cysteine, salicylic acid, hydrogen peroxide and dimethylsulfoxide (DMSO) were purchased from Sigma-Aldrich Chemie GmbH (Buchs, Switzerland). Phosphate Buffer Saline (PBS)

were purchased from Thermo Fisher Scientific (Buchs, Switzerland). Catalase polyclonal antibody was purchased from Proteintech (Rosemont, USA). Hydroethidine (HE) and coumarinboronic acid (CBA) were purchased from Adipogen AG (Liestal, Switzerland). PANC-1, CFPAC-1 BxPC-3 cells were purchased from ATCC. H6c7 was purchased from Kerafast.

## **2.2 Cell culture**

CFPAC-1 and BxPC-3 cells were maintained in RPMI-1640 medium supplemented with 10% (v/v) fetal bovine serum and 1% Penicillin-Streptomycin (P/S). PANC-1 was maintained in high glucose DMEM supplied with 10% (v/v) fetal bovine serum and 1% Penicillin-Streptomycin (P/S). H6c7 was maintained in a keratinocyte serum-free medium following the manufacturer's instructions (Keragast, Cat#ECA001-FP).

The cells were cultured at 37°C in the humidified incubator (Thermo Fisher Scientific) with 5% CO<sub>2</sub>.

## **2.3 In vivo animal studies**

All animal experiments were in accordance with institutional guidelines and approved by the Kantonale Veterinärämte Zürich (Project license: ZH184/2018, ZH043/2019). Mice were housed in a pathogen-free animal facility at the Institute of Molecular Systems Biology at ETH Zurich. The animals were maintained in a temperature-controlled room (22°C), with humidity at 55% and on a 12 h light-dark cycle (lights on from 6 a.m. to 6 p.m.). Mice were fed a standard laboratory chow diet and water ad libitum, and the age of the mice is indicated in the Figures. Both male and female mice were used in this study.

*Kras*<sup>G12D</sup> and *Ptf1a*<sup>Cre</sup> GEMMs have been described before<sup>22-23</sup>. All mice were maintained on a mixed background. The genotyping results are showed in the supplemental information (Fig.S1). The related genotyping primers (5'-3'):

Ptf1 <sup>cre</sup> _1	ATAGGCTACCTGGCCATGC
Ptf1 <sup>cre</sup> _2	GGGCTGCAGGAATTCGTGC

Jax Kras common_R	CTG CAT AGT ACG CTA TAC CCT GT
Jax Kras Mut_F	GCA GGT CGA GGG ACC TAA TA

Primary pancreatic acinar cell isolation method can be found in our previous work.<sup>6</sup>

## 2.4 Histology

Tissues were fixed with 4% PFA overnight, then embedded in paraffin follow standard protocol and sectioned at the thickness of 3.5  $\mu$ m. Haematoxylin and eosin staining were performed using the standard protocol.

## 2.5 Mouse primary acinar cell isolation

Mice were sacrificed, sprayed with 70% EtOH and the pancreas was dissected. The pancreas was digested with 0.5 mL 2 mg/mL collagenase P at 37°C for 25 min with shake. Digestion was stopped by washing with ice-cold 1xHBSS supplemented with 5% FBS. Filter the cells through 500  $\mu$ m and 100  $\mu$ m mesh. The resulting cells were gently loaded on top of 50 mL falcon tube containing 20 mL 1xHBSS plus with 30% FBS. Primary acini clusters were pelleted by centrifugation at 67.08 xg for 2 min.

## **2.6 Catalase treatment of PANC-1 and BxPC-3 cells (negative control experiment for COH formation)**

The cells were maintained until they reached 80% confluence. Then 500 Units/mL catalase (Sigma Aldrich, Cat#C9322, dissolved in 50 mM potassium phosphate buffer at pH 7.0) were added to the fresh cell culture medium. Control cells received 50 mM potassium phosphate buffer treatment. The cells were treated with catalase or 50 mM potassium phosphate buffer for 24 hours followed by mass spectrometry analysis. Cell densities were the same in experimental and control groups.

## **2.7 Positive control experiment for COH formation**

Cells were aliquoted into five 1mL tubes and were centrifuged to remove DMEM. Next, cells were added separately with different concentrations of H<sub>2</sub>O<sub>2</sub> (0, 88, 176, 264, 352 μM), and were finally incubated with coumarin-7-boronic acid (CBA) (500 μM) for 30 minutes. After the incubation, the cells were lysed by MeOH and centrifuged (67.08 xg, 4 minutes). The supernatant was collected for COH analysis.

## **2.8 Cancer Genome Atlas (TCGA) dataset analysis**

Gene expression data of normal pancreatic tissues (GTEx; n = 167) and pancreatic ductal adenocarcinoma (TCGA-PDCA; n = 178) were downloaded from UNSC Xena (<https://xena.ucsc.edu/>). Differential expression analysis was performed using DESeq2. Gene Set Enrichment Analysis (GSEA v3.0) of GO biological processes was performed on normalized counts.<sup>24</sup>

## 2.9 qPCR

Total RNA was isolated with Trizol following the manufacturer's protocol (Sigma, Cat# T9424). The resulting RNA was treated with DNase I (Thermofisher Scientific, Cat# AM1906). Then the RNA was reverse transcribed using High-Capacity cDNA Reverse Transcription Kit (Thermo Fisher Scientific, Cat# 4368813) by using random primers. Quantitative PCR was performed by KAPA SYBR FAST qPCR assay (Sigma, Cat# KK4611) in a LC480 II Lightcycler (Roche). Results were normalized to 36B4 or GAPDH mRNA levels.

## 2.10 MTT assay

Cell viability was determined by MTT [3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyl-2H-tetrazoliumbromid] (Sigma, Cat# M5655) assay after treated with catalase and 50 mM potassium phosphate buffer for 24 hours. Briefly, MTT solution in 1x PBS was added to each well of 96 well-plate at the final concentration of 0.5 mg/mL. The plate was protected from light and incubated for 3 hours at 37 °C. The medium was then aspirated and the dark-blue formazan was dissolved with dimethylsulfoxide (DMSO, Sigma, Cat# D4540). Optical density was measured with a spectrometer at 490 nm. The raw luminescence data were normalized to the adenovirus control.

## 2.11 Immunoblots (IB)

Cells were lysed in RIPA buffer (150 mM sodium chloride, 50 mM Tris-HCl pH7.4, 0.1% SDS, 1 mM EDTA, 1% NP-40, 0.5% sodium deoxycholate) freshly supplied with protease inhibitors cocktail and PhosSTOP. The protein concentration was determined using the Bradford protein assay. Equal amount of proteins was subjected to 10-15% SDS-PAGE analysis. The immune signal was detected by the ECL kit (Thermo Scientific). The amounts of protein were quantified by Image J software.

Antibodies used in this study:

## **2.12 Mass spectrometry analysis of H<sub>2</sub>O<sub>2</sub> at the population level**

Cells were incubated with Coumarin-7-boronic acid (CBA) (500 μM) for 30 minutes to enable the full reaction between CBA and H<sub>2</sub>O<sub>2</sub> in the cells to produce 7-hydroxycoumarin (COH) (Figure S2a). After the incubation, DMEM was removed by centrifugation (67.08 xg, 4 minutes), and the cells were resuspended in PBS. Then the cells were centrifuged again (67.08 xg, 4 minutes) to remove PBS, and lysed by MeOH. After centrifugation at 3286.92 xg for 5 min at 4 °C, the supernatant was collected for COH analysis.

## **2.13 Mass spectrometry analysis of •OH at the population level**

Cells were incubated with salicylic acid (500 μM) for 30 minutes to enable the full reaction between salicylic acid and •OH in the cells to produce 2,3-DHBA (Figure S2b). After the incubation, DMEM was removed by centrifugation (67.08 xg, 4 minutes), and the cells were resuspended in PBS. Then the cells were centrifuged again (67.08 xg, 4 minutes) to remove PBS, and lysed by MeOH. After centrifugation at 3286.92 xg for 5 min at 4 °C, the supernatant was collected for 2,3-DHBA analysis.

## **2.14 Mass spectrometry analysis of O<sub>2</sub><sup>•-</sup> at the population level**

Cells were incubated with hydroethidine (HE) (500 μM) for 30 minutes to enable the full reaction between HE and O<sub>2</sub><sup>•-</sup> in the cells to produce 2-hydroxyethidium (2OH-E<sup>+</sup>) (Figure S2c). After the incubation, DMEM was removed by centrifugation (67.08 xg, 4 minutes), and the cells were resuspended in PBS. Then the cells were centrifuged again (67.08 xg, 4 minutes) to remove PBS, and lysed by MeOH. After centrifugation at 3286.92 xg for 5 min at 4 °C, the supernatant was collected for 2OH-E<sup>+</sup> analysis.

## **2.15 Analysis of metabolites in cell lysates**

Cells were centrifuged (67.08 xg, 4 minutes) to remove DMEM and were resuspended in PBS. PBS was then removed by centrifugation (67.08 xg, 4 minutes), and lysed by MeOH. After centrifugation at 3286.92 xg for 5 min at 4 °C, the supernatant was diluted by MeOH: water=1:1(v/v) and collected for metabolites analysis.

## **2.16 Mass Spectrometry**

Mass spectra were acquired in positive ion mode, with an LTQ Orbitrap mass spectrometer (Thermo Fischer Scientific, San Jose, U.S.A.), in fullscan mode at a resolution of 30,000 FWHM (at m/z 400) with a mass tolerance specified to be < 10 ppm. The mass-to-charge range was set to 100–1000, capillary voltage is 50 V, tube lens voltage is 120 V, capillary temperature is 320°C, AGC target = 10<sup>6</sup>. Mass spectra were acquired using 1 microscans and a maximum injection time of 10 ms.

## 2.17 Data analysis

The raw MS data generated from the mass spectrometer was recorded with Xcalibur™ version 2.2 software (Thermo Fisher Scientific, San Jose, U.S.A.). The MSConvert software (ProteoWizard, v3.0)<sup>25</sup> was used to convert MS raw data (.raw) to mzML format. The converted mzML format file is imported into R (version 4.0.2 (2020-06-22)),<sup>26</sup> and preprocessed using self-developed R code with the package MALDIquant for the preprocessing steps. All the spectra from a sample were integrated and the intensity was averaged for each detected peak, signal to noise ratio of 3 was used for peak picking, peak alignment and binning were done on all the processed files. From this procedure, a matrix containing the relevant information was obtained for every condition. Spectra were normalized using lipids signals, 782.57 (PC(36:4)) for cell lines and 780.55 (PC(34:2)) for mice cells. After normalization, intensities were log<sub>2</sub> transformed. Two-sided T-test was made for three repetitions for each condition for each cell type. Fold change was also calculated and the information obtained was used to do the volcano plots, and constructed with the package EnhancedVolcano. Significant features were selected as those with a P-value lower than 0.05, and a fold change higher than 2 or lower than -2. Using the information from MS/MS, a few metabolites were assigned and bar plots with dots were done for the compounds, each dot represents the average normalized intensity of a biological replicate, and the bar is the mean value, the error bars present the standard deviation of the three samples, the graphs were designed with the program Prism (Graph Pad v9.4.1).

## 2.18 Metabolite assignments

Preliminary peak assignments were done by comparing the observed accurate  $m/z$  values with the theoretical mass in online databases, including the Human Metabolome Database (<http://www.hmdb.ca/>), LIPID MAPS (<http://www.lipidmaps.org>) and the METLIN metabolite database (<https://metlin.scripps.edu/>). The MS/MS spectra of specific parent ions obtained by ESI-MS were then used to confirm the assignment of metabolites by matching the characteristic product ions to MS/MS spectra in the databases, see Figure S6 and Table S1.

## 3. Results and Discussion

### 3.1 Mass Spectrometry Reveals High Levels of H<sub>2</sub>O<sub>2</sub> in Pancreatic Cancer.

In order to study different ROS species in PDAC, the state-of-art pancreatic cancer model *Kras*<sup>G12D/+</sup> *Ptf1a*<sup>Cre/+</sup> (KC) was used (Figures 1a and S2). Mice pancreatic tissue was collected for histological and mass spectrometric analysis (Figure 1b). By haematoxylin and eosin (H&E) staining, we found that one-month-old KC mice already showed clear signs of cancer initiation as there are some acinar-to-ductal-metaplasia (ADM) lesions, but the progression of PDAC was much more aggressive in 6-month-old KC mice than one-month-old KC mice (Figures 1c-f), consistent with our previous work.<sup>6</sup> Importantly, by using electrospray (ESI)-MS, we found H<sub>2</sub>O<sub>2</sub> to increase around 2.5-fold in freshly isolated primary acinar cells from 6 months-old KC mice compared to littermate controls (Figure 1i). In contrast, O<sub>2</sub><sup>•-</sup> and •OH levels remain almost unchanged in KC animals when compared to their littermate controls (Figures 1g and

h). Furthermore, the effect of aging<sup>27</sup> on the release of H<sub>2</sub>O<sub>2</sub> by mitochondria was also observed in KC mice (Figure 1j).

These interesting findings in KC mice encouraged us to monitor different ROS species in human cells. We found that H<sub>2</sub>O<sub>2</sub> instead of •O<sub>2</sub>• or •OH increased around 10-fold in human PDAC cells (PANC-1 cells and CFPAC-1 cells) compared to normal human pancreatic H6C7 cells (Figures 1k-m).

To verify that COH is the reaction product formed by CBA and H<sub>2</sub>O<sub>2</sub>, we added 500 μM CAB and different concentrations of H<sub>2</sub>O<sub>2</sub> to cell lysates, as shown in Figure S3. The intensity of COH increased linearly with increasing H<sub>2</sub>O<sub>2</sub> concentration. To confirm that H<sub>2</sub>O<sub>2</sub> was indeed the oxidant we measured by ESI-MS, we added H<sub>2</sub>O<sub>2</sub> specific inhibitor catalase to eliminate H<sub>2</sub>O<sub>2</sub>, and found that the oxidation of CBA to COH was suppressed (Figure S4), supporting the notion that CBA did not react with other species. These observations support that H<sub>2</sub>O<sub>2</sub>, rather than the other two ROS, is dysregulated in both mouse and human pancreatic cancer cells.

**Figure 1.** Acinar cells bearing the oncogenic *KRAS* mutation and PDAC cells produce more  $H_2O_2$ . (a) Genetic strategy for generating oncogenic *KRAS* mutation in pancreatic acinar cells. (b) Schematic diagram of the experiment design. (c) 1 month-old control mice pancreatic tissue section. (d) 1 month-old KC mice pancreatic tissue section (arrow indicates ADM area). (e) 6 month-old control mice pancreatic tissue section. (f) 6 month-old KC mice pancreatic tissue section. (g) Relative  $O_2^{\bullet -}$  intensity in 6 month-old control mice and KC mice. (h) Relative  $\bullet OH$  intensity in 6 month-old control mice and KC mice. (i) Relative  $H_2O_2$  intensity in 6 month-old control mice and KC mice. Mean  $\pm$  SD. \*\*,  $p < 0.01$ . (j) Relative  $H_2O_2$  intensity in 1 month-old control mice, 1 month-old KC mice, 6 month-old control mice and 6 month-old KC mice. Mean  $\pm$  SD. \*,  $p < 0.05$ . (k) Relative  $O_2^{\bullet -}$  intensity in PANC-1, CFPAC-1 and H6C7. (l) Relative  $\bullet OH$  intensity in PANC-1, CFPAC-1 and H6C7. (m) Relative  $H_2O_2$  intensity in PANC-1, CFPAC-1, H6C7 and BxPC-3. Mean  $\pm$  SD. \*\*,  $p < 0.01$ .

### 3.2 *KRAS*<sup>G12D</sup> Mutations Produce More H<sub>2</sub>O<sub>2</sub> and Reduce *CAT* Expression Levels in PDAC Cells.

Oncogenic *KRAS* mutations were well-documented as driving oncogenic events in pancreatic cancer<sup>28</sup>. We found that mice with *KRAS* mutations harbour more H<sub>2</sub>O<sub>2</sub> than mice without *KRAS* mutations (Figure 1i). Moreover, *KRAS* wildtype BxPC-3 and H6C7 cells harbour much less H<sub>2</sub>O<sub>2</sub> compared to the *KRAS* mutant PANC-1 as well as CFPAC-1 cells (Figure 1m). Therefore, we speculated that the *KRAS* mutation may be the reason for the enrichment of H<sub>2</sub>O<sub>2</sub> in PDAC cells. To this end, we re-expressed the *KRAS*<sup>G12D</sup> gene in BxPC-3 cells and found the activation of *KRAS*-Erk signalling (Figure 2a). As expected, the intensity of H<sub>2</sub>O<sub>2</sub> in BxPC-3 was significantly increased, roughly 2-fold, in the *KRAS*<sup>G12D</sup>-expressed group compared to the empty vector group (Figure 2b), which suggested that the oncogenic *KRAS* mutation led to the production of H<sub>2</sub>O<sub>2</sub> in PDAC cells.

Superoxidase dismutase (*SOD*), *CAT* (Catalase) and glutathione peroxidase (*GPx*) are genes associated with H<sub>2</sub>O<sub>2</sub> production and consumption<sup>29</sup>. O<sub>2</sub><sup>•-</sup> is converted into H<sub>2</sub>O<sub>2</sub> by *SOD*, and H<sub>2</sub>O<sub>2</sub> is converted into water by *CAT* or *GPx* (Figure 2c). We found that the mRNA levels of *SOD* and *GPx* were not regulated by the oncogenic *KRAS* mutation, but the levels of *CAT* were controlled by the oncogenic *KRAS* mutation in both KC mice and BxPC-3 cells (Figures 2d-f). We further investigated the relevance of *CAT* levels in human PDAC, using 178 PDAC and 167 normal pancreatic tissue datasets from The Cancer Genome Atlas (TCGA) and the Genotype-Tissue Expression (GTEx) projects, respectively. As expected, we found that the expression levels of *CAT* decreased around 40% in human PDAC biopsies (Figure 2g). These data suggest that oncogenic *KRAS* mutations not only produce more H<sub>2</sub>O<sub>2</sub>, but also silence *CAT* expression levels in PDAC cells.

**Figure 2.** *KRAS*<sup>G12D</sup> mutations produce more H<sub>2</sub>O<sub>2</sub> and suppress *CAT* expression levels in PDAC cells. (a) Immunoblot (IB) analysis of total cell lysate isolated from BxPC-3 cells transfected with pBaBe-Vector and pBaBe-HA-*KRAS*<sup>G12D</sup> plasmids by Lipofectamine 2000 for 48 hours. HA and KRAS antibodies were used to monitor the HA-*KRAS*<sup>G12D</sup> expression efficiency. Erk1/2 and phos-Erk1/2 antibodies were used to detect the activity of the main downstream signaling pathway of KRAS. Ponceau S is used as a protein loading control. ### **3.3 Enriched H<sub>2</sub>O<sub>2</sub> Modifies Metabolites in Pancreatic Cancer Cells.**

The effect of ROS on lipids and other metabolites has been widely reported<sup>30</sup>. We also reported that lipids metabolism was dysregulated in PDAC<sup>7</sup>. Thus, we hypothesized that increased H<sub>2</sub>O<sub>2</sub> levels may affect the metabolites in PDAC cells. To this end, we investigated the effect of H<sub>2</sub>O<sub>2</sub> inhibition by catalase on chemical modifications of metabolites in pancreatic cancer cells, including PANC-1, BxPC-3 and KC mice, using ESI-MS. Mass spectra of PANC-1, BxPC-3 and KC mice, as well as PANC-1, BxPC-3 and KC mice treated with catalase are shown in Figure 3.

We performed MS/MS on the 50 most intense signals from each cell lysate in an attempt to identify key metabolites. Positive identifications, based also on agreement with MS/MS data in databases, are shown in Figure S6 and in Table S1. As shown in Figures 3a and b, PC(34:1) ( $m/z$  760.59, [M+H]<sup>+</sup>), PC(36:4) ( $m/z$  782.57, [M+H]<sup>+</sup>) and PC(38:5) ( $m/z$  808.58, [M+H]<sup>+</sup>) are the three predominant lipids in PANC-1. However, when PANC-1 cells were treated with catalase, the lipid profile changed dramatically. For instance, the intensity of PC(38:5) was higher than that of PC(34:1) before catalase treatment, whereas the intensity of PC(38:5) became lower than that of PC(34:1) after treatment with catalase. In contrast, Figure S5a and b show that, compared with the mass spectrum of BxPC-3, the mass spectrum of BxPC-3 cells treated with catalase does not change significantly. In addition to cell lines, we also detected lipid modifications in KC mice and control mice (Figure 3h and i). We found that PC(34:2) ( $m/z$  780.55) and PC(38:7) ( $m/z$

804.55) were the predominant lipids in control mice and KC mice, but their distribution is different. For example, the intensity of PC(34:2) was higher than that of PC(38:7) in control mice, while the intensity of PC(34:2) was lower than that of PC(38:7) in KC mice. The mass spectra of PANC-1 cells and acinar cells with KRAS mutation show a very clear change after suppressing H<sub>2</sub>O<sub>2</sub>, but the mass spectra of BxPC-3 cells without the KRAS mutation did not change significantly after the H<sub>2</sub>O<sub>2</sub> was suppressed.

To clearly demonstrate the effect of H<sub>2</sub>O<sub>2</sub> on metabolites in cells, we used volcano plots to visualize the significantly different features in PACN-1 cells and PACN-1 cells treated with catalase (Figure 3c), and in control mice and KC mice (Figure 3j). For example, valine (m/z 140.07, [M+Na]<sup>+</sup>), nordeoxycholic acid (m/z 379.28, [M+H]<sup>+</sup>), LysoPC(18:3) (m/z 518.32, [M+H]<sup>+</sup>) and PC(40:4) (m/z 860.61, [M+Na]<sup>+</sup>) displayed statistically significant differences between the PACN-1 cells and PACN-1 cells treated with catalase (Figures 3d-g). In control mice and KC mice, for instance, valine (m/z 140.07, [M+Na]<sup>+</sup>), nordeoxycholic acid (m/z 379.28, [M+H]<sup>+</sup>), palmitoylcarnitine (m/z 400.34, [M+H]<sup>+</sup>) and PC(30:2) (m/z 724.49, [M+Na]<sup>+</sup>) are metabolites with statistical differences between normal acinar cells and acinar cells bearing the oncogenic KRAS mutation (Figures 3k-n). MS/MS data on some of these compounds can be found in Figure S6 and Table S1.

Our data not only revealed that enhanced H<sub>2</sub>O<sub>2</sub> affected the metabolites in human and murine pancreatic cancer cells, but also highlight that the valine, nordeoxycholic acid, palmitoylcarnitine, LysoPC(18:3), PC(40:4) and PC(30:2) may be required for PDAC development.

**Figure 3.** Metabolic changes caused by  $H_2O_2$ . (a) average mass spectrum of PANC-1 cell lysate. (b) average mass spectrum of a lysate of PANC-1 cells treated with catalase. (c) volcano plot of the correlations between the P-values and fold changes for the metabolite signals in PANC-1 cells and PANC-1 cells treated with catalase. Relative intensities of (d) valine, (e) nordeoxycholic acid, (f) LysoPC(18:3) and (g) PC(40:4) in PANC-1 cells and PANC-1 cells treated with catalase are shown in the bar plots. (h) average mass spectrum of an acinar cell lysate. (i) average mass spectrum of a lysate of acinar cells bearing the oncogenic KRAS mutation. (j) volcano plot of the correlations between the P-values and fold changes for the metabolite

signals in normal acinar cells and acinar cells bearing the oncogenic *KRAS* mutation. Relative intensities of (k) valine, (l) nordeoxycholic acid, (m) palmitoylcarnitine and (n) PC(30:2) in normal acinar cells and acinar cells bearing the oncogenic *KRAS* mutation are shown in the bar plots.

### **3.4 Hydrogen Peroxide Promotes the Survival of *KRAS* Mutant PDAC Cells.**

The above results revealed that  $H_2O_2$  was dysregulated in PDAC cells. To investigate whether targeting  $H_2O_2$  is beneficial for PDAC treatment, we first inhibited  $H_2O_2$  in PANC-1 cells and BxPC-3 cells with catalase. As shown in Figures 4a and b, inhibition of  $H_2O_2$  decreased the cell viability of PANC-1 cells, but inhibition of  $H_2O_2$  had no significant effect on the cell viability of BxPC-3 cells. To prove that  $H_2O_2$  is indeed the oxidant, we added catalase to inhibit  $H_2O_2$ . When  $H_2O_2$  was inhibited, no COH was detected (Figures S7a and b). To further demonstrate that the decrease in PDAC cell viability was caused by the inhibition of  $H_2O_2$ , we inhibited all ROS in PDAC cells with N-acetylcysteine (NAC), which is the general ROS scavenger. As shown in Figures S7c-f, the cell viability of PANC-1 cells decreased when all ROS in the cells were removed, while the cell viability of BxPC-3 cells did not change significantly, consistent with the results obtained from the inhibition of  $H_2O_2$  alone. In line with this, we found that catalase treatment induced more cell death indicated by trypan blue assay and apoptosis revealed by apoptosis marker cleaved caspase 3 in PANC-1 cells (Figures 4c and d), indicating that  $H_2O_2$  promotes the survival of PDAC cells.

**Figure 4.** Hydrogen peroxide promotes the survival of KRAS mutant PDAC. (a-b) Relative cell viability detected by MTT assay in PANC-1 and BxPC-3 cells. Mean  $\pm$  SD. \*\*,  $p < 0.01$ . (c) Trypan Blue assay indicating cell death in PANC-1 cells. Mean  $\pm$  SD. \*\*,  $p < 0.01$ . (d) IB analysis of total cell lysate isolated from PANC-1 cells described in (a). Cleaved caspase 3 antibody was used to monitor the apoptosis level. Hsp 90 used as protein loading control.

## 4. Conclusions

ROS play important roles in tissue homeostasis, cellular signalling, differentiation, and survival in both healthy and disease context. Literature reported that ROS were also dysregulated and had important roles in PDAC, while the detailed roles of specific ROS in PDAC had remained unclear. In this study, we applied powerful mass

spectrometry, genetic and molecular biology, as well as genomic sequencing data analysis techniques to analyze KC mice and human PDAC cells. We found that  $H_2O_2$ , but not other ROS, was dysregulated in PDAC. Moreover, we identified that the oncogenic *KRAS* mutation promoted  $H_2O_2$  production and silenced *CAT* levels in PDAC, which may be the main reason for  $H_2O_2$  enrichment in PDAC cells. Furthermore, we identified that  $H_2O_2$  strongly affected the metabolites profile and promoted the survival of PDAC cells. These findings not only highlight that targeting  $H_2O_2$  might be beneficial for PDAC therapy, but also remind us to study ROS individually with novel techniques instead of taking ROS as one single biochemical entity.

## 5. Supporting information

**Figure S1.** Probes and formed products from different ROS. (a)  $\text{H}_2\text{O}_2$  reacts with CBA to generate COH detected as  $\text{C}_9\text{H}_5\text{O}_3^-$ ,  $m/z$  161.0239. (b)  $\cdot\text{OH}$  reacts with salicylic acid to generate 2,3-DHBA detected as  $\text{C}_7\text{H}_5\text{O}_4^-$ ,  $m/z$  153.0187. (c)  $\text{O}_2\cdot^-$  reacts with HE to generate 2OH-E $^+$  detected as  $\text{C}_{21}\text{H}_{20}\text{N}_3\text{O}^+$ ,  $m/z$  330.1601.

## B. Curriculum Vitae

### Personal information

Name: Qinlei Liu

Date of birth: 29 December 1993

Place of birth: Sichuan Province, China

Email: liuqinleiseven@gmail.com

### Education

#### August 2019 – October 2022

PhD in Analytical Chemistry, Department of Chemistry and Applied Biosciences, ETH Zurich, Switzerland

Supervisor: Prof. Dr. Renato Zenobi

#### September 2016 – June 2019

MSc in Analytical Chemistry, Department of Chemistry, Sichuan University, Sichuan Province, China

Supervisor: Prof. Dr. Chengbin Zheng

#### September 2012 – June 2016

BSc in Chemistry, Department of Chemistry and Materials Science, Sichuan Normal University, Sichuan Province, China

### Teaching Experience

February 2020 – June 2022 Teaching Assistant at the Laboratory Class in Analytical Chemistry at ETH Zurich, teaching infrared spectroscopy

### Awards

2021 Chemistry Travel Award by SCNAT and SCS
